Criteria for inclusion in the *Programme Grants for Applied Research* journal

Reports are published in *Programme Grants for Applied Research* (PGfAR) if (1) they have resulted from work for the PGfAR programme, and (2) they are of a sufficiently high scientific quality as assessed by the reviewers and editors.

Programme Grants for Applied Research programme

The Programme Grants for Applied Research (PGfAR) programme, part of the National Institute for Health Research (NIHR), was set up in 2006 to produce independent research findings that will have practical application for the benefit of patients and the NHS in the relatively near future. The Programme is managed by the NIHR Central Commissioning Facility (CCF) with strategic input from the Programme Director.

The programme is a national response mode funding scheme that aims to provide evidence to improve health outcomes in England through promotion of health, prevention of ill health, and optimal disease management (including safety and quality), with particular emphasis on conditions causing significant disease burden.

For more information about the PGfAR programme please visit the website: <http://www.nihr.ac.uk/funding/programme-grants-for-applied-research.htm>

This report

The research reported in this issue of the journal was funded by PGfAR as project number RP-PG-0606-1048. The contractual start date was in August 2007. The final report began editorial review in July 2014 and was accepted for publication in September 2015. As the funder, the PGfAR programme agreed the research questions and study designs in advance with the investigators. The authors have been wholly responsible for all data collection, analysis and interpretation, and for writing up their work. The PGfAR editors and production house have tried to ensure the accuracy of the authors' report and would like to thank the reviewers for their constructive comments on the final report document. However, they do not accept liability for damages or losses arising from material published in this report.

Background: Depression is common in patients with coronary heart disease (CHD) but the relationship is uncertain. In the UK, general practitioners (GPs) have been remunerated for finding depression in CHD patients; however, it is unclear how to manage these patients.

Objectives: Our aim was to explore the relationship between CHD and depression in a GP population and to develop nurse-led personalised care (PC) for patients with CHD and depression.

Design: The UPBEAT-UK study consisted of four related studies. A cohort study of patients from CHD registers to explore the relationship between CHD and depression. A metasynthesis of relevant literature and two qualitative studies [patients' perspectives and GP/practice nurse (PN) views on management of CHD and depression] helped develop an intervention. A pilot randomised controlled trial (RCT) of PC was conducted.

Setting: Thirty-three GP surgeries in south London.

Participants: Adult patients on GP CHD registers.

Interventions: From the qualitative studies, we developed nurse-led PC, combining case management and self-management theory. Following biopsychosocial assessment, a PC plan was devised for each patient with chest pain and depressive symptoms. Nurses helped patients address their most important related problems. Use of existing resources was promoted. Nurse time was conserved through telephone follow-up.

Main outcome measures: The main outcome of the pilot study of our newly developed PC for people with depression and CHD was to assess the acceptability and feasibility of the intervention and to decide on the best outcome measures. Depression, measured by the Hospital Anxiety and Depression Scale – depression subscale, and chest pain, measured by the Rose angina questionnaire, were the main outcome measures for the feasibility and cohort studies. Cardiac outcomes in the cohort study included: attendance at rapid access chest pain clinics, stent insertion, bypass graft surgery, myocardial infarction and cardiovascular death. Service use and costs were measured and linked to quality-adjusted life-years (QALYs). Data for the pilot RCT were obtained by research assistants from patient interviews at baseline, 1, 6 and 12 months for the pilot RCT and at baseline and 6-monthly interviews for up to 36 months for the cohort study, using standard questionnaires.

Results: Personalised care was acceptable to patients and proved feasible. The reporting of chest pain in the intervention group was half that of the control group at 6 months, and this reduction was maintained at 1 year. There was also a small improvement in self-efficacy measures in the intervention group at 12 months. Anxiety was more prevalent than depression in our CHD cohort over the 3 years. Nearly half of the cohort complained of chest pain at outset, with two-thirds of these being suggestive of angina. Baseline exertional chest pain (suggestive of angina), anxiety and depression were independent predictors of adverse cardiac outcome. Psychosocial factors predicted the continued reporting of exertional chest pain across the 3 years of follow-up. Costs were slightly lower for the PC group but QALYs were also lower. Neither difference was statistically significant.

Conclusions: Chest pain, anxiety, depression and social problems are common in patients on CHD registers in primary care and predict adverse cardiac outcomes. Together they pose a complex management problem for GPs and PNs. Our pilot trial of PC suggests a promising approach for treatment of these patients. Generalisation is limited because of the selection bias in recruitment of the practices and the subsequent participation rate of the CHD register patients, and the fact that the research took place in south London boroughs. Future work should explicitly explore methods for effective implementation of the intervention, including staff training needs and changes to practice.

Trial registration: Current Controlled Trials ISRCTN21615909.

Funding: This project was funded by the National Institute for Health Research (NIHR) Programme Grants for Applied Research programme and will be published in full in *Programme Grants for Applied Research*; Vol. 4, No. 8. See the NIHR Journals Library website for further project information.

Plain English summary

Many people with coronary heart disease (CHD) are depressed and research on people who have had a heart attack found that depression increases the chance of further heart attacks. The UPBEAT-UK team conducted research with people on general practitioner CHD registers in 33 south London practices to: examine any link between CHD, depression and worse future heart disease; and develop case management by practice nurses for people with CHD and depression.

We followed 803 people with CHD for up to 3 years, assessing them for depression, chest pain and worsening of heart disease, and also measured care costs. We asked patients, GPs and nurses how people with CHD and depression should be treated. From this, we developed care designed for each person called 'personalised care' (PC). We tested it in 41 people (while 40 people received their usual care from GPs) with chest pain and depression, to assess how acceptable it is, whether or not it helps and what the costs would be. PC was acceptable to people, and those who received it reported less chest pain 6 and 12 months later. Costs were lower following PC but the difference was not statistically significant.

Just under half of those with CHD had chest pain. Depression was frequent, but anxiety was more common and increased the chances of both heart attacks and death.

We conclude that further research is needed to understand the links between anxiety, chest pain and heart disease, and to further develop our promising findings that PC can be helpful in reducing chest pain in general practice.

Scientific summary

Background

Coronary heart disease (CHD) and depression are predicted to be the two leading causes of health-related disability worldwide by 2020. In 2007, the annual societal costs of depression in England were estimated to be £7.5B, projected to be £12B by 2026. The King's Fund estimated that £1 in every £8 spent on long-term conditions is for comorbid mental health. Depression is more prevalent in patients with CHD but the nature of this relationship is uncertain. Previous research conducted in secondary care on patients after cardiac events, such as myocardial infarction (MI), has shown that depression post MI worsens cardiac outcome, increasing the likelihood of cardiac events and cardiac-related death. Established treatments for depression, such as selective serotonin reuptake inhibitors and cognitive-behavioural therapy, have only a moderate effect in CHD patients and no effect on cardiac outcomes. There is an ongoing debate about whether or not case finding for depression in CHD should be conducted in GP practices in England and Wales, and whether or not general practitioners (GPs) should be remunerated for this. It is also unclear how GPs should best manage these patients. Furthermore, it is unclear whether or not the association between depression and adverse cardiac outcome seen in secondary care also exists in primary care. There is no knowledge of the long-term outcome of depression in this patient group or whether or not the association with adverse cardiac outcome remains constant over time. GP CHD registers, by their very nature, may represent a population of people who have survived previous cardiac events and hence have a milder, but still progressive, cardiac disorder, allowing various factors to be studied in the prognosis of depression.

Objectives

The UPBEAT-UK study was designed to determine the prevalence, incidence and course of depression in patients on GP CHD registers, and describe the course and pattern of cardiac outcomes (including chest pain, cardiac interventions, MI and cardiovascular mortality) and costs, testing for any association between depression and adverse cardiac outcomes. The UPBEAT-UK study was also designed to elicit the perspectives of patients with CHD and depression, understand the perspectives of their GPs and practice nurses (PNs) about current management, and develop and test the acceptability, feasibility and cost-effectiveness of a new intervention for CHD register patients with chest pain and depression that could be delivered within current primary care practice.

Method

The UPBEAT-UK study consisted of four related work packages:

1. a metasynthesis of previous research and a qualitative study of GP and PN views on current management of patients with CHD and depression
2. a qualitative study of patients' perspectives of their biopsychosocial needs
3. a pilot trial to assess the acceptability, feasibility and cost-effectiveness of an intervention based on nurse-led personalised care (PC) for people with CHD experiencing current chest pain and depression and determine best outcome measures
4. a 3-year cohort study of patients on GP CHD registers to explore prevalence, incidence, course and costs of depression, course and pattern of chest pain and cardiac outcomes, and the relationship between depression and cardiac outcomes.

Setting

Thirty-three GP surgeries in south London.

Participants

Adults aged ≥ 18 years, registered on GP CHD Quality and Outcomes Framework registers. Patients from 16 surgeries were recruited to the cohort study and patients from an additional 17 practices were recruited for the pilot randomised controlled trial (RCT). Patients from the cohort study were recruited for the qualitative study, as were GPs and PNs for the qualitative study of professionals.

Intervention

We applied the Medical Research Council framework for the development of complex interventions to develop an evidence-based intervention informed by patient and clinician preferences and established theory. This was a primary care-based nurse-led PC intervention. Following a face-to-face assessment, nurses trained in behaviour change techniques facilitated patients to address the problems that they perceived as most important to them and which related to their CHD or depression. Existing resources for CHD or depression-related problems were identified and used by nurses. Follow-up was by telephone.

Main outcome measures

- Pilot RCT: acceptability (Patient Satisfaction Questionnaire, participation rates), feasibility (recruitment and randomisation), potential range of effects [Hospital Anxiety and Depression Scale – depression subscale (HADS-D), Rose angina questionnaire], costs and quality-adjusted life-years (QALYs).
- Cohort: depression (HADS-D), chest pain (Rose angina questionnaire) and a range of cardiac outcomes including attendance at rapid access chest pain clinics, coronary artery stent insertion and bypass grafting, MI and cardiovascular death (extracted from the GP records) and costs.
- Data sources: data were obtained from patient interviews, GP records and national and local authority sources.

Results

Metasynthesis and qualitative study of general practitioners and practice nurses

We identified seven qualitative and 10 quantitative studies, none of which concerned depression and comorbid physical illness. It appeared that GPs and PNs were aware of a relationship between mood and social problems but were unsure of their role in addressing this.

General practitioners and PNs considered that distress after a cardiac event resolves spontaneously; if it endured, or became severe, it was treated as depression. Psychosocial problems were viewed as contributing to depression in CHD, but clinicians expressed uncertainty about their role and responsibility in addressing these problems. An individualised approach was favoured, but clinicians were unsure how to achieve this.

Qualitative study of patients

Thirty patients with depressive symptoms on the CHD register, some of whom reported chest pain, were interviewed. A theme of loss, both before and after the onset of CHD, underpinned accounts (e.g. interpersonal loss, loss of health and of control). Participants felt 'depressed' by what they perceived

as a 'medicalisation' of loneliness and by the experience of ageing and ill health. Some believed that their GP would not be able to help with their complex health and social issues. Talking therapies and interventions providing social interaction, support and exercise (e.g. cardiac rehabilitation) were thought helpful, whereas antidepressants were not.

Pilot randomised controlled trial

Seventeen practices were approached by the Greater London Primary Care Research Network and all agreed to participate. Practice recruitment was quicker than expected, indicating that a definitive trial would be feasible. Of 3325 patients on CHD registers, 1001 consented to contact, of whom 81 were eligible and randomised (41 intervention, 40 control), although three patients were wrongly randomised as they had no chest pain. Recruitment for a definitive RCT seems promising, although it would be from a large pool of potential participants and randomisation was largely successful. As this was a pilot trial, it was not powered to detect efficacy of the intervention. We therefore do not report *p*-values and report findings, which should be explored further in a definitive RCT. Both groups showed improvement in depression (HADS-D score) at all time points, with mean scores moving from moderate depression at baseline to mild depression at 12 months. A mixed-effects model showed no significant differences between groups over time for any measure of depression and confidence intervals (CIs) were wide, so an effect in favour of either group cannot be ruled out. The most notable difference between PC and treatment as usual (TAU) was in chest pain on the Rose angina questionnaire. The percentage of patients no longer reporting chest pain was 37% in PC versus 18% in usual care at 6 months, and 31% in PC versus 19% in usual care at 12 months. PC participants also made fewer accident and emergency (A&E) visits (24% PC vs. 38% TAU), although missing data concerning the reason for these visits makes this difficult to interpret. Self-efficacy was also improved more in PC. Health economic analyses showed that total costs in the intervention arm were lower than usual care but QALYs were also lower. These differences were not statistically significant. Overall, PC seemed to be acceptable and feasible.

Cohort study

Sixteen south London practices, with 142,648 patients, participated in the cohort study. Of this population, 2% (2938/142,648) were on GP CHD registers. A total of 803, after invitation by GP letter, participated, representing 27% (803/2938) of those on the CHD registers. The mean age of participants was 71 years, 70% were male and 87% were white. Participants reported multiple social problems, multimorbidity and disabilities, including problems with general pain and discomfort (53%, 425/803), poor mobility (49%, 391/803) and difficulties with intimate relationships (38%, 302/803). A total of 573 patients (71.3%) provided complete data to 36 months and a further 136 provided data up to 48 months. The analyses reported here are of data up to 36 months.

Of these patients, 7% had depressive disorder at baseline and 13% had depressive symptoms. There were 12% who had an anxiety disorder comprising: panic disorder (< 1%), generalised anxiety disorder (3%), and mixed anxiety and depressive disorder (8%). Twenty-five per cent of patients had anxiety symptoms yet only 3% of people were recorded as having anxiety in the GP records. The incidence of depression was 130 per 1000 person-years at risk for men and 90 for women, so males were nearly 1.5 times more likely to develop depression. Over 36 months, just over half of patients had a cardiac intervention (e.g. stent insertion or graft), 11% had a MI and 5% of patients died from a cardiovascular cause. Incidence rates of cardiac death were 12.7 per 1000 person-years for men and 9.3 per 1000 person-years for women. Standardised mortality ratios compared with the general population were 1.13 (95% CI 0.62 to 1.90) and 1.87 (95% CI 0.81 to 3.70) for men and women, respectively.

In total, 44% of the cohort complained of chest pain at outset, 66.8% of these being exertional, which is suggestive of angina. Baseline exertional chest pain (Rose category 2) was associated with all cardiac outcomes. For rapid access chest pain clinics, relative risk ratio (RRR) 4.00 (95% CI 1.84 to 8.72); cardiac interventions (RRR 7.51, 95% CI 3.74 to 15.10); MI and cardiovascular death (RRR 3.72, 95% CI 1.54 to 9.01).

Anxiety was an independent predictor of MI and cardiovascular death (RRR 3.93, 95% CI 1.95 to 7.90). Depression did not predict any cardiac outcomes.

We found there were different risk profiles for continued reporting of non-exertional (Rose category 1) and exertional (Rose category 2) chest pain across the 3 years of follow-up. Risk factors for the former were: female sex [odds ratio (OR) 2.80, standard deviation (SD) 7.19], asthma (OR 3.34, SD 1.98) and anxiety (OR 1.33, SD 0.62). Good quality of life was protective (OR 0.98, SD 0.01). For exertional pain, the risk factors were: exertional pain at baseline (OR 28.07, SD 7.14) and anxiety (OR 0.65, SD 0.38). Good quality of life was similarly protective for exertional pain (0.98, SD 0.01).

The average cost over the 36 months for patients with depressive symptoms at baseline was double that for patients without depressive symptoms at baseline. Inpatient services dominated costs at baseline and follow-up. Statistically significant predictors of higher societal costs were: depressive disorder (measured by the Clinical Interview Schedule – Revised), white ethnicity, housing problems, relationship problems, self-reported current cancer and baseline health-care costs.

Conclusions

Nearly half of all patients on GP CHD registers were found to have current chest pain and this was strongly associated with concurrent social problems. Patients who reported chest pain at the outset of the study were more likely to have further chest pain over the following 3 years and to have more adverse cardiac outcomes, such as needing stent insertion, bypass graft surgery, having a MI or dying of a cardiac cause. Although depression was common, episodic and associated with increased costs, anxiety disorder was more common and found to be a stronger predictor of worse cardiac outcome and mortality than depression, so there is a pressing need to better understand this link. More sophisticated models linking the patterns of depression, anxiety and chest pain are needed to understand the associations between anxiety, chest pain and adverse cardiac outcomes. We have a unique cohort data set to allow us to achieve this.

General practitioners and nurses seem currently uncertain how best to manage patients' symptoms in the context of the many psychosocial problems in their CHD patients. PC promoting self-management proved to be acceptable and feasible, improved patient self-efficacy, reduced chest pain and was associated with fewer overall costs than usual care (e.g. fewer A&E attendances). PC combining case management and self-management with an extra emphasis on anxiety needs to be further piloted and definitively tested with PNs, working closely with colleagues in practices. Many nurses told us they had little extra current capacity, so this would need to be built into practice plans. PC combining self-management with an extra emphasis on anxiety could also be piloted and definitively tested with psychological well-being practitioners in Improving Access to Psychological Therapy, although they would need training and supervision in long-term conditions and behavioural change techniques. Future work should explicitly explore methods for effective implementation of the intervention, including staff training needs and changes to practice.

Trial registration

This study is registered as ISRCTN21615909.

Funding

Funding for this study was provided by the Programme Grants for Applied Research programme of the National Institute for Health Research.

Chapter 1 Overview of the programme

We have previously published the rationale and protocol for the UPBEAT-UK programme,¹ how we subsequently developed the intervention for the pilot randomised controlled trial (RCT) from the findings of the earlier work packages² and the final protocol for the pilot RCT.³ This chapter opens with a statement on patient and public involvement (see *Patient and public involvement*). We have then summarised the introductory sections of the published introductory papers^{1–3} (see *Background*), which has been updated with references to more recent literature. In *Aims and objectives of the programme*, the key objectives of the four work packages are outlined. Finally, all currently published papers from the UPBEAT-UK study are listed in *Acknowledgments*.

Patient and public involvement

We were able to recruit patient and public involvement representatives from mental health organisations (Service User Research Enterprise and Charlie Waller Memorial Trust), but we were unfortunately unable to recruit any patient representatives with coronary heart disease (CHD) to our programme over its duration, despite frequent attempts at contacting relevant organisations, such as the British Heart Foundation, through our research team members, including our cardiologist member. However, it would have been quite a commitment for a patient representative to give up 5–7 years and this may have been the limiting factor. This has been a disappointment, particularly as there could be an increasing role for providing such support from relevant third-sector organisations. The patient and public involvement initiative was in its infancy when these studies were set up; 10 years on we may have had a more positive response from patient-based voluntary organisations that would have become more familiar with the required task.

Background

Coronary heart disease and depressive disorders are two of the leading causes of burden of disease and disability, as measured by disability-adjusted life-years. It has been estimated, using data from the World Health Organization, that by 2030, unipolar depressive disorders and CHD will be the second and third leading cause of burden of disease, respectively, trailing only human immunodeficiency virus/acquired immunodeficiency syndrome.⁴ Surprisingly, however, while there are several guidelines worldwide for the management of both conditions separately, there are no clear guidelines on how best to manage patients who have both comorbid conditions. A key recommendation of a specially convened US Preventive Task Force on the management of depression and CHD was to conduct RCTs of stepped care to generate much-needed evidence.⁵ So far, RCTs have shown that treating depression in CHD slightly improves depressive symptoms and quality of life, but has no effect on mortality.⁶ Furthermore, cardiac rehabilitation (CR) together with mental health treatments may reduce depression, CHD events and mortality risk.⁷ Despite this, limitations in the current literature show that further research is needed to improve psychological and cardiac outcomes in these patients.

Coronary heart disease

Coronary heart disease, especially when chest pain is present, often causes functional limitation, distressing symptoms, is often life-threatening and requires long-term management, mostly in primary care. Many patients with CHD have a documented history of myocardial infarction (MI) or coronary artery disease shown at angiography. CHD also causes 70% of heart failure with fatigue and shortness of breath. CHD mainly comprises three groups of patients with: chronic stable angina (with exertional chest pain), post MI, and heart failure with a hierarchy of physical and emotional effects. The researchers at Imperial College London, on behalf of the Public Health Observatories of England, have developed a prevalence model.⁸ They estimate the prevalence of CHD in primary care trusts and at local authority level to be 5.80%, although this number rises to 16.08% in people aged 65–74 years, and 21.91% in those ≥ 75 years.

In the south London primary care trusts of Lambeth, Southwark and Lewisham, the prevalence is 3.30%, 3.50%, and 3.85%, respectively ($\geq 15\%$ in those aged 65–74 years and $\geq 22\%$ in those ≥ 75 years).⁸

Depression

Depression is a major public health problem responsible for around 100 million lost working days in England and Wales each year and costing £9B per annum.⁹ In the UK, depression is a common reason for consulting a general practitioner (GP). Up to one-third of people who visit the GP have mental health problems, and 90% of those are treated only in primary care.¹⁰

Depression incurs a 50% increase in the cost of long-term medical care after controlling for the severity of the physical illness,¹¹ and this may relate to the link between depression and adverse health risk behaviours such as smoking, diet, lack of exercise and poor self-care. Depression may exacerbate the perceived severity of symptoms and this, in turn, can bring about an increase in health service utilisation. Treating depression and improving outcomes for depression has been shown to reduce health costs in people with physical illness.¹¹ Furthermore, collaborative care and individualised management of patients with depression and chronic conditions, such as diabetes and CHD, has shown to improve both medical outcomes and depression.¹²

Depression and coronary heart disease comorbidity

Depression occurs in up to 20% of patients with CHD and depression increases the incidence and recurrence of CHD, acute coronary syndromes and mortality.⁵ A systematic review by Nicholson *et al.*¹³ places the pooled relative risk (RR) of future CHD associated with depression at 1.81; however, the authors stop short of calling depression an independent risk factor for developing CHD, owing to the heterogeneity of studies.

The clear association that exists between these two conditions has led to a long discussion about the precise nature of the relationship. Ageing (which increases the odds of both conditions), lifestyle factors, inflammation pathways, heart rate variability, impaired arterial repair and several genes, are just some of the mechanisms that could play a role.¹⁴ Nevertheless, the link is well established. A review by the American Heart Association¹⁵ recently recommended that depression be considered an independent risk factor for adverse outcomes in patients with acute coronary syndrome, given the strength of the evidence in the current literature.

The presence of concurrent physical illness, such as CHD, is known to reduce the likelihood of major depression being recognised by GPs.¹⁶ Diagnosing depression in elderly primary care patients is hampered by conditions such as heart disease and the drugs to treat these conditions, which can have mood-destabilising effects.¹⁷ The natural history, morbidity and mortality of depression in primary care CHD populations are unknown.

As GP practices keep separate registers for their patients with heart failure, this programme of research is solely concerned with CHD and patients on CHD registers rather than patients on heart failure registers. This also means that the focus of research in terms of physical symptoms is purely on chest pain rather than on fatigue and dyspnoea.

Managing depression and coronary heart disease

Although there are several treatment options for managing depression in primary care that are endorsed by the National Institute for Health and Care Excellence (NICE)¹⁸ [e.g. antidepressant medication, supervised exercise, guided self-help, problem-solving, computerised cognitive-behavioural therapy (CBT), group or individual CBT or interpersonal therapy], the treatment preferences of CHD patients are unknown, as are primary care professional treatment preferences. A recent US working party on the management of depression in CHD concluded that RCTs comparing stepped depression care with treatment as usual (TAU) for patients with CHD and depression are needed.⁵

It remains unclear how GPs and practice nurses (PNs) should best manage patients with depression and CHD. Previous research, which has been largely from the USA, has focused on treating depression with antidepressant medication, psychological treatment, case management and collaborative care. Because of the absence of available evidence in this area, we decided to conduct a systematic review and metasynthesis of available evidence in work package 1.

Medication and psychological treatment

Two large US-based trials^{19,20} have also provided an indication in post-hoc subgroup analyses that there may have been cardiovascular benefit from the management of the depression using antidepressant medication and it has been suggested that this may be owing to an effect on platelet activation.^{21,22} Mortality seems to have been reduced in those whose depression improved or in those who took sertraline (Zoloft®, Pfizer) in one study.^{23,24} This evidence was influential in the introduction of financial incentive payments to English GPs for screening consecutive CHD patients for comorbid depressive disorder under the General Medical Services Quality and Outcomes Framework (QOF), although this was abandoned in 2013.

Case management

Case management has been shown to improve outcomes for depression in primary health-care settings,²⁵ but there has been no research to determine the cost-effectiveness in patients with CHD. Case management is 'taking responsibility for following-up patients; determining whether patients were continuing the prescribed treatment as intended; assessing whether depressive symptoms were improving; taking action when patients were not adhering to guideline-based treatment or were not showing expected improvement'.²⁶ It consists of five essential components:²⁵

1. identification of patients in need of services
2. assessing individual patient's needs
3. developing personalised treatment plans
4. co-ordination of care
5. monitoring outcomes and altering care when favourable outcomes are not achieved.

Collaborative care

An early, large US-based multicentre study of stepped collaborative depression care showed positive results regarding depression in older people as did another US trial of collaborative depression care in diabetics in motivated patients.^{27,28} However, the latter trial did not improve diabetic outcome.²⁸ Subsequently, during the life of the UPBEAT-UK programme, Katon *et al.*,¹² using collaborative care, were able to demonstrate in a groundbreaking study the improvement of depression, systolic hypertension, glycosylated haemoglobin and blood lipids. As they applied rigorous nurse care to the depression, hypertension, diabetes and lipid abnormalities, it is not clear to what extent the management of depression contributed to the improvement of the physical outcome measures. Since then, and again in the lifetime of the UPBEAT-UK programme, it has been demonstrated that collaborative care as a model works in an English setting for depressive disorder, albeit with a modest effect size.²⁹ Collaborative care usually requires the collaboration of psychiatrists or other mental health professionals working together with their primary care colleagues to supervise case management by dedicated case workers. These care workers are usually mental health professionals brought in for the purpose of overseeing the case management and liaising with the patient's primary and secondary care workers.

The overall design of the UPBEAT-UK programme led to a pilot RCT in order to inform a future definitive RCT of the cost-effectiveness of PN-led personalised case management in primary care for patients with CHD and depression. A pilot RCT was necessary to determine whether or not case management by PNs for this population would be a feasible and acceptable intervention compared with TAU in terms of both depression and cardiac outcomes.

The first step was to judge the acceptability, feasibility and likely effect of case management to inform whether or not to conduct a future definitive RCT. As any future potential definitive RCT would be a complex intervention, it was necessary to follow Medical Research Council (MRC) guidelines³⁰ for the development of a complex intervention using a programme of related work packages to develop and test a new nurse-led personalised case management practice for depression and CHD in primary care. The overall scientific framework for the UPBEAT-UK programme was the MRC framework for the development and testing of complex interventions.³⁰ This framework has four stages:

Stage 1: development concerns the identification of existing evidence in order to develop the intervention to a point where it can be expected to have a beneficial effect. Conducting a systematic literature review or metanalysis is recommended if such a review does not already exist. This is followed by the identification and development of theory with a rationale for the proposed intervention and likely change process. The development of theory may build on existing evidence and be supplemented with new (often qualitative) research. This should then lead to a testable model with a specific intervention, process and likely outcomes.

Stage 2: feasibility and piloting involves assessing the feasibility and acceptability of the new complex intervention and of the evaluation methods, including acceptability, compliance, delivery, randomisation, recruitment, retention, and observed variability around changes in the primary outcome to inform the power calculation for a subsequent definitive RCT. The pilot RCT examines key criteria for a definitive RCT.

Stage 3: evaluation involves the evaluation of the intervention using appropriate design usually by a definitive RCT.

Stage 4: implementation involves the routine implementation of the new intervention, surveillance, monitoring and long-term follow-up.

Stages 1–4 should be seen as cyclical rather than linear, with results from any stage informing not just subsequent stages but previous stages in continuous improvement and increasingly higher-level evaluation.³⁰ The UPBEAT-UK programme mainly involves stages 1 and 2 outlined above.

The four inter-related UPBEAT-UK work packages are:

1. a review of previous work in the area and qualitative study of GP and PN treatment preferences for this patient group
2. a qualitative study of patients with CHD and comorbid depression treatment preferences
3. a pilot RCT of nurse-led case management for depressed primary care patients with CHD
4. a 4-year cohort study of patients with CHD.

In this introductory chapter, the detailed methods will be described in each work package chapter.

Aims and objectives of the programme

Work package 1

A review and metasynthesis of the existing literature and a qualitative study of health professionals' perceptions of distress and depression in patients with CHD.

Objectives

1. To review and conduct a synthesis of existing literature on primary care management of CHD and depression.
2. To explore primary care professionals' views on distress and depression in patients with CHD.
3. To explore their current management strategies and attitudes to a range of treatments in relation to this patient group.
4. To provide guidance on the design and implementation of a PN-led case management depression intervention.

Work package 2

Study of patients' perceptions of distress and depression in patients with CHD.

Aims

The aim was to elicit patients' perceptions of their psychological state as linked to their CHD and explore their views on appropriate treatments for distress or depression in the context of their CHD.

Sample

Up to 50 people were to be purposively sampled from the cohort study based on age, sex, practice, CHD status, and depression severity.

Work package 3

Pilot RCT of primary care case management for depressed patients with symptomatic CHD (sCHD).

Objectives

The objectives of this pilot were:

1. Clinical efficacy of case management.
To explore whether or not case management for primary care patients with sCHD and depression, when delivered by nursing professionals, may be more effective than TAU.
2. Sample size calculation.
To calculate estimates of the location of the mean and variability around the mean [standard deviation (SD)] for the primary outcome measure (depression).
3. To enable selection of the most appropriate primary and secondary outcome measures.
4. Integrity of the study protocol.
To test all procedures for a definitive effectiveness RCT, for example:
 - i. inclusion/exclusion criteria
 - ii. training of staff in the administration and assessment of the intervention
 - iii. to test data collection forms and questionnaires
 - iv. to ensure the acceptability of the questionnaires to participants, along with comprehensibility, appropriateness, clarity and consistency
 - v. patient information documents and consent forms were also tested, as was inter-rater reliability between researchers.

5. Randomisation procedure.
To test the randomisation process and acceptability of randomisation to primary care professionals and participants.
6. Recruitment and consent.
To test the recruitment method and the consent rate for participants, and explore barriers to recruitment of both practices and participants.
7. To determine the acceptability of the intervention and the trial to practices and participants.
To determine the possible sources of contamination, and to develop a standardised manual for case management for use in the definitive RCT. To make an informal assessment of the degree to which the intervention can be standardised and whether or not therapist effects are likely to be a major factor.

Work package 4

Cohort study

Objectives

The objectives were:

1. to determine prevalence, incidence rate and risk factors of depression in primary care patients with CHD
2. to explore and describe the course, relationship, prognosis and current management of physical and depressive symptoms in primary care patients with CHD and comorbid depression over a 3- to 4-year period
3. to determine the effect of comorbid depression on mortality, symptom severity, quality of life, disability, pain, service use (at all levels) and service costs, and lost employment costs in primary care patients with CHD.

Chapter 2 General practitioners' and practice nurses' perceptions of distress and depression in patients with and without symptomatic coronary heart disease: literature review and qualitative interview study (work package 1)

Plan

In the previous, introductory, chapter, we described the existing evidence demonstrating putative mechanisms linking CHD and depression. We have described how depression has previously been associated with worse cardiac prognosis and an increased cardiac mortality. We described a need to better understand the relationship between the two disorders and a pressing global public health need to improve integrated primary care for people with both disorders.

In this chapter we describe how we gathered evidence from primary care professionals – GPs and PNs – concerning their current practice, views and experience of managing depression in people with CHD, which would chiefly be people who were included on their general practice-based QOF CHD registers. We also asked a sample of south London GPs and PNs how they currently managed such patients and if there was a need for an enhanced, probably PN-led, intervention in their own general practice for their registered CHD patients complaining of chest pain and depression and if so, what they would want from such a new stepped care intervention.

Prior to commencing this qualitative study, we searched for and synthesised existing qualitative and quantitative research in general practice on the management of people with depression and CHD and used this to inform the design of our own qualitative study, especially the topics for discussion. The evidence we gathered from the metasynthesis and both qualitative studies with professionals and patients would subsequently be used to inform the development of our UPBEAT-UK pilot/feasibility intervention according to MRC guidelines³⁰ for the development of complex interventions. How the findings from these earlier studies informed the development of our feasibility/pilot study is described in *Chapter 4*.

Methods

Metasynthesis of published qualitative and quantitative research

Review aim

We considered that issues important to the effective primary care-based management of depression in general are likely to be important when managing depression in people who also have CHD, but that there may also be additional factors to consider when both conditions are comorbid in an individual. By systematically investigating similarities and differences in previous findings across published studies of primary care professionals' experience of managing depression, our metasynthesis could provide high-quality evidence to inform our proposed qualitative study focused on primary care professionals' depression management for people with CHD. This review, therefore, aimed to identify barriers to and facilitators of the effective management of depression in people with or without comorbid physical health problems in primary care settings.

Review methods

Terms relating to depression, primary care and primary care professionals' attitudes to depression were combined to form a search strategy (see *Appendix 1*), which was adapted for four databases (MEDLINE, EMBASE, PsycINFO and British Nursing Index and Archives). We also searched the reference lists of identified papers. This review was conducted early in the programme (search date 30 June 2008). We planned to use the findings to inform the GP and PN interviews reported in *Qualitative interview study of general practitioners' and practice nurses' views and experience of managing depression in coronary heart disease*. Hence we have not updated this review, but note that the paper in which the results were published³¹ has been highly cited. To obtain the most relevant and up-to-date evidence, we included only publications concerning studies that had been conducted in the UK and published after 2000. This was a pragmatic method of including a manageable number of studies and ensured we obtained data on current and relevant attitudes (2000 is after the publication of the National Service Framework for Mental Health³²). We only included studies set in the UK as we felt that these would be most likely to inform an intervention that could be implemented in UK primary care; that is, studies conducted in other settings were excluded as we felt it would be difficult to understand the impact of different health-care delivery systems on their findings, which would impair their translation to UK primary care. Both qualitative and quantitative studies were included. We assessed the identified abstracts for relevance and then we quality rated them according to standard recognised criteria.^{33,34} We did not use quality judgements to exclude papers but tested the strength of findings by examining whether or not they were supported by studies in the upper tertile of scores.³⁵ We extracted key themes and synthesised them using principles drawn from meta-ethnography²⁴ and guidelines for producing narrative syntheses.³⁶

Review results

Our first finding was that no relevant paper concerning GP or PN views about depression and comorbid physical illness of any kind was identified, despite our use of a comprehensive search strategy. Seven qualitative³⁷⁻⁴³ and 10 quantitative studies of the management of primary depression were included.⁴⁴⁻⁵³ *Figure 1* shows the flow of studies through the review process.

Summary of review findings

Details of our metasynthesis findings have been published in an open access journal by Barley *et al.*³¹ in 2011. *Table 1* shows the included studies. The key themes and how they translate across the included studies are detailed in *Table 2*. Both tables were also published Barley *et al.*² In summary, we identified seven key themes, which were all supported by at least one good-quality study and by both qualitative and quantitative data. The first theme concerned professionals' understanding of depression; depression was either seen as a normal response to life events, or biomedical explanations were given. The second theme concerned how clinicians recognise depression and highlighted how they struggle to distinguish between 'normal' distress and depression requiring treatment. Management options for depression made up the third theme, with clinicians expressing a preference for talking therapy over antidepressants, but also for being able to take a personalised approach. Shame and stigma around depression arose as a fourth theme; it was felt that this prevented some patients seeking help, but the authors of one study considered that this may be constructed to hide a reluctance to explore depression, with patients arising from a desire to avoid feelings of powerlessness when management options seem limited. A lack of interprofessional working within primary care was the main finding within our fifth theme. Our sixth theme showed that clinicians may have ambivalent attitudes to managing depression; this was reflected in our final theme which showed that although primary care clinicians felt that they needed more training in mental health, when this was offered, they did not take it up. Key findings in relation to these themes were that GPs and PNs consider depression and its diagnosis to be complex. There was ambivalence about the use of case finding tools in primary care settings, such as those that were recommended at the time for use in people with CHD and diabetes in the QOF.⁵⁶ However, most studies identified in our search did not discuss these as they had been conducted and published prior to the introduction of financial incentives under the QOF of the UK GP contract⁵⁶ in 2006 when their use became routine.

TABLE 1 Characteristics of included studies

Reference	Participants (response rate)	Aim	Setting and sample selection	Methods of collecting clinician data and research perspective (quality assessment)
Qualitative studies				
Johnston <i>et al.</i> , 2007 ³⁷	32 GPs (24%)	Identify issues of importance to GPs in depression management	28 GP practices in and around Southampton (plus two GPs in Leicester)	Semistructured interviews; grounded theory (10/10)
Murray <i>et al.</i> , 2006 ³⁸	18 GPs, 7 PNs	Identify perceptions of depression older people	18 south London primary care teams in five Boroughs, purposive sampling based on setting (socioeconomic/ ethnic groups served) and practice type	In-depth, semistructured interviews; grounded theory (9/10)
Burroughs <i>et al.</i> , 2006 ³⁹	9 GPs, 3 PNs	Explore how primary care professionals and patients view late-life depression	One PCT in NW England, purposive sampling but criteria not stated	Semistructured interviews; constant comparison (7/10)
Maxwell <i>et al.</i> , 2005 ⁴⁰	20 GPs	Explore GPs' experience of recognising and managing depression	11 practices from a 'random' sample of 55 in Scotland – four NHS board areas	Semistructured interviews; critical realist perspective (5/10)
Pollock and Grime, 2003 ⁴¹	19 GPs	Investigate GPs' views on consultation time and depression management	Eight West Midland practices – purposeful selection based on socioeconomic/ geographical setting and patient list size	Semistructured interviews (8/10)
Chew-Graham <i>et al.</i> , 2002 ⁴²	35 GPs in teaching practices (66%)	Explore GPs' attitudes to the management of depression in deprived vs. affluent populations	22 inner city GPs vs. 13 suburban and semirural GPs in NW England, purposive sampling based on practice size	Semistructured interviews; constant comparative qualitative analysis (9/10)
Rogers <i>et al.</i> , 2001 ⁴³	10 GPs	Explore GPs' views on depression management	Eight practices in Greater Manchester (inner city/ suburban)	In-depth, semistructured interviews (5/10)
Quantitative studies				
Kendrick <i>et al.</i> , 2005 ⁴⁴	17 GPs	Explore associations between GP treatment, depression severity and patient characteristics	Six GP practices in Southampton (nine practices approached)	Questionnaire (devised for this study) ratings of patient characteristics and GP treatment decisions completed following consultation (3/7)
Shiels <i>et al.</i> , 2004 ⁴⁵	Four GPs – three principals, one assistant	Compare GPs' and male patients' assessments of depression	One practice in a prosperous rural area of Cheshire	Questionnaire (devised for this study) completed following consultation (3/7)
Naji <i>et al.</i> , 2004 ⁴⁶	442 PNs (56.2%)	Assess PNs' knowledge, attitudes, training and management of depressed patients	One in two sample of Scottish general practices (428 practices)	Questionnaire – DAQ ⁵⁴ plus some questions developed for this study, postal survey (5/7)

TABLE 1 Characteristics of included studies (*continued*)

Reference	Participants (response rate)	Aim	Setting and sample selection	Methods of collecting clinician data and research perspective (quality assessment)
Manning and Marr, 2003 ⁴⁷	202 GPs (50%)	Compare expectations of GPs and patients in the management of relapse of depression	GP practices 'across the UK'	Questionnaire – devised for this study by a market research company, postal request sent with link to online questionnaire (2/7)
Byng <i>et al.</i> , 2003 ⁴⁸	274 GPs	Describe GPs' beliefs about their management of depression	All GPs in Lambeth, Southwark and Lewisham Health Authority (inner city)	Likert scale questionnaire – (devised for this study, but piloted on 15 GPs) (4/7)
Oladinni, 2002 ⁴⁹	61 GPs (60%)	Assess the attitudes of GPs towards depression	Inner city GP surgeries in Lambeth (group and single handed), 'randomly' selected	Questionnaire (DAQ) – postal survey (2/7)
Telford <i>et al.</i> , 2002 ⁵⁰	1703 GPs (48%)	Survey GPs' perception of the availability/quality of primary care and community-based services for depressed people. Identify barriers to provision of services	11 health authorities – one from each English region and one each from Northern Ireland, Wales and Scotland. Urban, rural, deprived and privileged	Questionnaire – devised for study, piloted on 131 GPs; postal survey (4/7)
Rothera <i>et al.</i> , 2002 ⁵¹	263 GPs (72%)	Examine the attitudes and practice of GPs in managing late-life depression	All 116 practices in Nottingham Health Authority	Postal survey (adapted for study from previous research) – responses to attitude statements and clinical vignettes (4/7)
Dowrick <i>et al.</i> , 2000 ⁵²	40 GPs	Test hypotheses that measures of GPs' confidence in identifying depression predict ability to identify depression and that GPs who prefer antidepressants prescribe more than those who prefer psychotherapy	Practices in Liverpool and Manchester	Questionnaire (DAQ), prescribing information, Likert scale depression ratings (3/7)
Livingston <i>et al.</i> , 2000 ⁵³	31 GPs, 24 PNs (12% of practices approached)	Assess acceptability and feasibility of an educational package concerning management of depression in old age	14 practices in West Essex, East Hertfordshire, Redbridge	Vignettes and questionnaire (adapted DAQ for older people) (baseline data only used in synthesis) (4/7)

DAQ, Depression Attitude Questionnaire; NW, North West; PCT, primary care trust.

TABLE 2 Extracted key themes and how they translate across the included studies

Summary second order constructs	Extracted key themes (authors' 'own words' or paraphrase) ⁵⁵	Summary translation across studies
Professionals' understanding of depression	<i>Constructing and resisting boundaries between depression, the self and 'normal' sadness</i> ³⁷	Depression may be seen as a normal reaction to distressing events or as pathology. Understandings of depression may conflict with management strategies
	<i>Depression as a normal response to life events</i> ⁴²	
	Inconsistency between beliefs and practice ⁴³	
	<i>Concerns surrounding the medicalisation of social problems</i> ⁴⁰	
	Depression as 'understandable reaction to distressing circumstances' ³⁸	
Recognising depression	<i>Aetiology of depression</i> ⁴⁹	Recognising depression is a complex process involving non-explicit subjective processes. Some see patients as reluctant to talk about their mood. Somatisation and/or comorbidity may complicate diagnosis. Receiving or giving a diagnosis of depression may benefit patients and GPs
	Nature of depression ^{49,52,53}	
	<i>Potential for secondary gain</i> ⁴²	
	<i>GPs' accounts of diagnosing and caring for patients with depression</i> ⁴⁰	
	<i>GPs' experiences of the diagnosis and management of depression</i> ⁴³	
	<i>consultation length/time and disclosure</i> ⁴¹	
	<i>Presenting complaints</i> ³⁸	
	<i>Distinguishing between depression and physical illness</i> ⁴²	
	<i>Avoidance of psychosocial problems</i> ³⁸	
	<i>Making the diagnosis</i> ³⁹	
Management strategies and tools	Accuracy of diagnosis ^{44-46,52}	Clinicians used antidepressants, talking therapies, listening and specialist services. Listening to depressed patients takes time; this may be a barrier to effective treatment, but one in-depth study contested this
	<i>GP goals and management approach</i> ³⁷	
	<i>GPs' accounts of diagnosing and caring for patients with depression</i> ⁴⁰	
	<i>GPs experience of the diagnosis and management of depression</i> ⁴³	
	<i>Importance of listening</i> ³⁷	
	Time as a barrier to listening ⁴²	
	Time and consultation length, disclosure, antidepressants, time management ⁴¹	
	<i>Management of late-life depression in primary care</i> ³⁹	
	Antidepressant use ^{44,47-49,52}	
	Role of specialist services ⁵⁰	
	Managing depression ⁴⁶	

TABLE 2 Extracted key themes and how they translate across the included studies (*continued*)

Summary second order constructs	Extracted key themes (authors' 'own words' or paraphrase) ⁵⁵	Summary translation across studies
Stigma and shame	<i>Stigma and shame</i> ³⁸ <i>depression still carries a stigma in this age group</i> ³⁹	Depression is perceived as stigmatising for some elderly people, especially those from ethnic minority groups
Relationships between professionals	<i>Primary care relationships</i> ³⁹ PNs' position in the practice ³⁸ Confusion over the role of and lack of access to specialist services ^{43,46,50} <i>scarcity of counselling resources</i> ⁴¹	There is confusion between primary care staff concerning their roles and responsibilities in the diagnosis and management of depression, and about the role of specialist services, which seems focused around lack of access
Attitudes to managing depression	<i>GP responses to chronic depression</i> ³⁷ <i>Interactional difficulties with depressed people</i> ⁴² Pessimistic about outcome ⁴³ Positive about outcome ^{40,41} Lack of confidence in managing depression ^{39,46,48,53} Ambivalence ^{49,51}	GPs and PNs experience frustration in managing depression. Some are confident about outcomes, but commonly there is ambivalence
Training needs	<i>without understanding the framework which underpins GPs views on 'depression' ... educational interventions directed at GPs will not improve patient outcome</i> ⁴² Lack of training and knowledge ^{39,46,50,51,53} <i>education efforts should focus on increasing GPs' sense of therapeutic optimism and providing them with sufficient skill in and knowledge of a range of psychological procedures</i> ⁵² <i>GPs would benefit from educational programmes that promote awareness of current treatment guidelines</i> ⁴⁷	Many PNs and some GPs say they need more training in managing depression, but this is not a priority for them. Training should be grounded in professionals' understandings of depression and should seek to improve attitudes to working with depressed people

Not all information was available for each study. Quality assessment score: higher score represents higher quality, qualitative studies scores out of 10 on critical appraisal skills programme checklist;³³ quantitative observational studies scores out of seven on a scale devised for this study (see *Appendix 2*; also published in our metasynthesis paper³¹).

All translated second-order constructs were supported by at least one good-quality study (bold references are studies scoring in top tertile of quality scores: qualitative studies $\geq 8/10$, quantitative studies $\geq 4/7$) and by both qualitative and quantitative studies.

The management of depression in a general practice setting is perceived as particularly complex when patients also present with concurrent social problems. GPs and PNs are very aware of the relationship between social problems and mood, but they are unsure of its exact nature and of their role in managing it. This uncertainty may be exacerbated by a lack of attention in guidelines concerning the influence of social problems on response to treatment.⁵⁴

There are ambivalent attitudes among GPs and PNs towards working with depressed people. This was reflected in a lack of confidence among some clinicians in their ability to manage mental health problems and the use of a limited number of management options. Most of these data are from GPs, perhaps because PNs may be less likely to manage depression than GPs; however, where depression is comorbid with physical illness PNs' views may be more important since they are taking an increasing lead in long-term condition management and particularly since practices began to be reimbursed for screening their diabetic patients and patients with CHD for depression under QOF, although this payment has since ceased.

There was also evidence that GPs avoid giving a diagnosis of depression based on a belief that some patients, especially older people and those of Caribbean or South Asian ethnicity, will feel stigmatised by it. One high-quality study³⁹ suggested, however, that concern about stigmatisation might be constructed to hide a reluctance to explore depression in order to avoid feelings of powerlessness when management options seem limited. At the time of the review, there were no data available to determine whether or not the same issues are important when managing patients with depression and comorbid physical illness. We, therefore, used the findings of this review to inform our planned study of GPs' and PNs' views and experience of managing depression in CHD.

Our review had demonstrated variation both between and within studies in views expressed concerning the management of depression in general. When considering the management of depression comorbid with CHD, we therefore decided to use a semistructured interview design. This would allow us to focus the interview on the topics that we considered important for informing our future intervention, while allowing participants to highlight topics important to them. Similarly, we realised that it would be important to use an iterative process for the data collection and analysis so that new themes arising in early interviews could be tested with later participants. The review findings also informed our topic guide (see *Appendix 3*). With the plan to develop a new intervention in mind, we ensured that each interview would cover three broad areas: defining depression in CHD, current management of depression in CHD and future management of depression in CHD. The key findings from our review related to each broad area were then used as prompts during the interview. In this way, we were able to test whether or not the findings of our review were relevant when considering depression in people who also had comorbid CHD and which issues would need to be addressed by the future CHD-specific intervention. For instance, when asking clinicians about how they defined depression in CHD, if they did not mention social problems (which we had found in our review to be important), we planned to prompt them to consider this issue. Hence, our metasynthesis allowed us to conduct a more relevant and focused qualitative study, which is described in the following section.

Qualitative interview study of general practitioners' and practice nurses' views and experience of managing depression in coronary heart disease

Study aim

This qualitative interview study was designed to help understand GPs' and PNs' views and experience of managing depression specifically when it is comorbid with CHD and to determine their preferences for our planned UPBEAT-UK nurse-led pilot intervention for people with CHD reporting chest pain, which could be angina or non-anginal chest pain, and depression.

Study methods

The initial sampling frame was the 16 GP practices participating in our cohort study, the design of which is described in *Chapter 5*. In recruiting the participants from these practices, we used a purposive, maximum variation approach to recruitment based on ethnicity, age, practice setting (inner city vs. suburban) and size (single handed vs. group). After several interviews, we noticed that participants often mentioned their involvement in our cohort study and we became concerned that this was an indication of heightened awareness of depression in CHD. From then on, only those clinicians from UPBEAT-UK practices who were not personally involved in the cohort study were interviewed. We also used a snowballing technique to identify GP and PN participants independent of the UPBEAT-UK research programme, that is, practices that we had not recruited to the cohort study.

We conducted individual semistructured interviews using a topic guide (see *Appendix 3*) based on the findings of our metasynthesis. We revised the topic guide iteratively: for instance, early participants introduced the problems of 'erectile dysfunction' and 'housebound patients' so we explored these topics with later participants. In order to ground opinions in practice, we asked participants to recall specific patients. We audio-recorded the interviews and transcribed them verbatim following written informed consent.

We conducted the interviews and analysis concurrently, and stopped recruitment at data saturation; that is, when no new themes or information emerged. We applied a staged procedure of thematic analysis to the data⁵⁷ adding rigour to the process with the techniques of constant comparison.⁵⁸ Three researchers (EB, JM and PW) independently coded the first interview and met to discuss preliminary descriptive codes. Following this, two of the researchers (EB and JM) independently applied these and, where appropriate, new codes to the following four transcripts when consistency in coding was achieved. Descriptive codes were collated into themes and a preliminary explanatory framework devised. This was then used as the basis for coding and for informing future interviews. Data for each theme were gathered and coded using computer software (NVivo version 8; QSR International, Warrington, UK). The robustness of themes was tested by examining differences and similarities between coded data.

Study results

In total, EB interviewed 10 GPs and 12 PNs. Male and female GPs were recruited but no male PNs were identified. GPs and PNs appeared to have similar views. We have published the findings of this study, including illustrative quotes and participant details, in open access journal papers by Barley *et al.*^{2,59} in 2012. The identified themes and topics discussed are listed in *Box 1* and the main findings are summarised below.

BOX 1 Themes identified and topics discussed during the GP and PN interviews**Theme: understandings of depression**

Distress vs. depression.

Distress or depression in CHD.

- vs. 'general depression'.
- vs. depression in other chronic diseases.
- CHD severity.
- Why some CHD patients become depressed.
- Disease impact.
- Individual difference.
- Social factors.
- Illness perceptions.

Impact of understandings on decisions to treat.

Theme: recognising and screening for depression

QOF questions.

- Benefits of QOF questions.

Reservations about QOF.

Clinical judgement.

Theme: assessing the severity of depression**Theme: current management of depression in CHD**

Management goals.

Current management options.

Choosing management options.

- Antidepressants.
- Talking therapy.
- Informal counselling.
- Exercise.
- Specialist NHS and community services.
- Other issues influencing management choices.

Theme: other issues in CHD depression

Erectile dysfunction.

Housebound patients.

Theme: future intervention for depression in CHD

Type of intervention.

Timing of intervention.

Who would deliver the intervention.

Summary of study results

Current attitudes and practices

General practitioners and PNs expressed diverse views, which indicates uncertainty about this topic. However, for most of the themes, a majority view could be identified, even if some individuals also offered alternative opinions. For instance, most of the participants appeared to consider CHD depression similar to other types of depression. Distress and depression were viewed, by most, as lying on a continuum of severity and/or chronicity. Individuals may 'naturally' become distressed following a diagnosis of CHD or a cardiac event, but only when the distress becomes severe and enduring is it seen as depression requiring treatment.

Most participants used the QOF questions to screen for depression, followed by a more detailed questionnaire, such as the Patient Health Questionnaire (PHQ-9) or the Hospital Anxiety and Depression Scale (HADS); however, use of additional questionnaires was not routine, even when responses to the QOF questions were positive (indicating possible risk of depression or a need for further exploration). In several practices, PNs did not have access to the detailed questionnaires, suggesting that there may be ambivalence towards their use. That most participants stressed the importance of their clinical judgement both in assessing depression and making management decision supports this. These findings are also supported by a recent study which also showed that although GPs used the questionnaires, they preferred to rely on their 'practical wisdom and clinical judgement' to guide their assessments.⁶⁰

The clinicians identified a range of management options for CHD depression. Antidepressants and talking therapies were most often cited. This is not surprising since each of these treatments or a combination is known to be effective for depression in other populations. There is also some evidence that selective serotonin reuptake inhibitors may have a direct beneficial effect on platelets,⁶¹ although only one GP in our study, who is also an academic, mentioned this. However, in CHD depression, many considered antidepressants as a last resort. This appeared to be owing to a perceived reluctance in CHD patients to accept them, either because of fear of stigma associated with mental health problems or to a general dislike of medications, which is exacerbated when patients are already taking multiple medications for their heart condition. Data from patients are required to assess the validity of this perception.

Talking therapies were favoured; however, only a few GPs differentiated between types of therapy. This suggests a lack of clarity about the aims and process of different therapies, which may reduce their ability to make appropriate referrals. Some patients had been observed to reject talking therapy, again out of fear of being stigmatised. However, the main barrier to the use of talking therapy was a lack of availability. This has been reported previously.⁴² It appears that the government's Improving Access to Psychological Therapies (IAPT) programme has not yet reached these south London practices.⁶²

Access to other management options that clinicians felt would improve aspects of CHD depression, such as exercise on referral schemes, clubs to reduce loneliness and agencies to help with financial or housing problems, varied widely between the practices. Furthermore, there was variation between clinicians in their knowledge of the availability of such options. This may reflect variation in clinicians' attitudes to managing problems that they believe are social in origin. Previous research³⁹ has identified 'therapeutic nihilism' in which clinicians feel helpless in the face of the complex social problems which impact on their patients' health. This attitude was seen in several participants in this study, although others actively sought to address social difficulties; one GP even expressed enjoyment in this aspect of her work. This latter attitude is encouraged in the government White Paper *Our Health, Our Care, Our Say: A New Direction for Community Health Services*.⁶³ This calls for greater integration of health and social care for patients with long-term conditions. One method may be 'social prescribing', which signposts patients to non-medical facilities and services available in the wider community, such as financial advice agencies and social clubs, which they can access to address the factors that influence their well-being. One practice involved in this study was providing this service, but our findings suggest that there is considerable scope to develop this for CHD depression in south London.

Informal counselling activities, such as reassurance and education, were performed by all the participants to some extent. With a few exceptions, most GPs were unwilling or unable to give much time to this. Some PNs reported that they did have the time, but even among these, there was doubt about how useful this was and many were left wondering how to progress and so would welcome guidance. Other nurses were open that they did not enjoy dealing with mental health problems or that they did not consider it to be part of their role either owing to lack of training or interest. These nurses would avoid raising the possibility of depression for fear of 'opening a can of worms' with which they felt unable to cope.

Future coronary heart disease depression intervention

This study has identified issues that should be addressed when designing a new CHD depression intervention. Findings from this study, along with those from previous work, may inform the type of intervention, the timing of the intervention and who should deliver the intervention.

Type of intervention

The participants were very clear that any intervention should be easily accessible. This was both in terms of being carried out locally, as they had observed a reluctance or inability in many patients to travel, and in terms of having clear and simple referral criteria so that clinicians would not be burdened by having to remember complex rules. Some participants reported difficulties remembering what treatment options and facilities were available for the multiple conditions that they managed; this could be a barrier to effective treatment.

The need for multiple treatment options was also stressed. This was so that options could be matched with the varying needs identified in individual CHD patients; because the participants recognised the importance of patient choice in improving adherence to treatment; and because clinicians value the opportunity to use their clinical judgement. Interventions that improve adherence to treatment were considered especially important as most of the clinicians considered that this was poor in CHD patients. However, although clinical judgement was valued, several nurses said they would favour the development of a protocol to guide their management decisions. This appeared to arise from their reported uncertainty as to what management options are available and appropriate for CHD depression.

Any new intervention should be evidence and theory based. Having goals and social support are known to be important to well-being.⁶⁴ Although no participant specifically mentioned goals, several noted that the causes of depression are specific to individuals and that to be effective, management plans should be patient driven. Evidence-based interventions that involve patients deciding which areas of their lives to address, such as problem-solving therapy, motivational interviewing or the technique of 'SMART goals', where individuals identify an area to change that is Specific, Measurable, Appropriate, Realistic and Timely, may therefore be useful in CHD depression and would most likely be accepted by GPs and PNs.

All participants mentioned the importance of social support. Some raised the role of the family in directing patients to care and helping with self-management. Most participants stressed the importance of combating isolation, which they felt is a determinant of depression in many CHD patients. This issue was considered to be especially relevant to housebound CHD patients, for whom, in many practices, no specific system of care had been devised. Identification by the patient of an individual who can support them in their self-management is a commonly used and effective strategy in several health-care interventions, for example weight loss and health training.⁶⁴ This type of intervention may be appropriate for many CHD patients and would be supported by GPs and PNs.

Cognitive habits are known to influence depression and, as such, CBT is now an established treatment for depression.⁶⁵ Similarly, in chronic disease, the ways in which individuals think about their illness and approach its management are known to influence outcome.^{66,67} Given the strength of this evidence, it is surprising that cognitive factors were not discussed in detail or by all participants. It appears that some of the clinicians considered physical and mental health separately and were more focused on the former.

Some participants, however, did mention the importance of cognitions such as illness perceptions and motivation or commitment to change in improving mood or health in general. Some participants said they or a colleague within the practice had had training in brief cognitive interventions such as '10-minute CBT'⁶⁸ or problem-solving therapy.⁶⁹ It appears that GPs and PNs vary in their understanding of and willingness to address cognitions when managing CHD depression. A new CHD depression intervention is likely to be most effective if it involves some level of cognitive change in the patient. Increasing self-efficacy, motivation, readiness and commitment to change, and changing illness perceptions have all been shown to improve outcomes in a range of chronic illness, including heart disease.⁶⁷ Some GPs and PNs may need education to accept such interventions.

Timing of the intervention

The participants were divided into whether an intervention for CHD depression would be most effective if delivered immediately following a cardiac event or several months later. The rationale for early intervention was to prevent the distress that they believed is commonly experienced following a CHD diagnosis or cardiac event from developing into a lasting depression. An early intervention should, therefore, focus on helping the patient come to terms with the feelings, observed by the clinicians, of shock and vulnerability and help them to adjust to changes in role or functioning. However, several clinicians felt that the majority of people recover without intervention. Previous research has shown that the medical condition and depression status of individuals within 6 months of MI fluctuate.⁵ It has been suggested by an expert panel on depression and CHD⁵ that a population whose depression is likely to remit spontaneously may not be the best group in whom to test the hypothesis that reducing depression will reduce the risk of CHD-related mortality and morbidity.

However, the panel also point out that early treatment with antidepressants, as opposed to depression symptom interventions, may be appropriate, to the extent that the former may have direct cardiovascular benefit. A further argument for early intervention concerns the role of illness perceptions in disease progression, which is well documented.⁶⁷ This issue was raised by two participants who felt that patients could be disabled more by their perceptions than by their actual CHD severity. There is some trial evidence to suggest that early modification of illness perceptions may lead to improved outcomes. In a small RCT,⁷⁰ inpatients who received a brief intervention designed to alter their perceptions about their MI had improved functional outcomes and reduced angina symptoms compared with controls at 3 months post discharge.

The participants' rationale for a later intervention, that is, some months after an event or initial diagnosis, was that if spontaneous recovery had not occurred, CHD-associated distress would have become chronic and therefore could be described as depression that needed treatment. Patients had, therefore, not adapted to having CHD or to its effects. Effects, such as loss of function or role due to CHD, and symptoms, such as erectile dysfunction (which may occur any time in CHD and up to 5 years prior to diagnosis,⁷¹ were identified as particular predictors of depression. These may need to be addressed at this time. It was also suggested that after a few months, when their medical condition has stabilised, the support available to CHD patients, such as CR and outpatient appointments is reduced. This may increase patients' risk of depression.

A complicating factor when deciding on the timing of a new intervention is that many participants were aware that their CHD patients were depressed prior to their diagnosis or cardiac event. This was explained in terms of the difficult social lives that many patients in south London lead; CHD was just another problem that added to their depression. An intervention that addressed multiple problems would therefore be necessary for such patients. This could be delivered at any time following diagnosis.

Findings from this study and from previous research therefore indicate that it is likely that different types of intervention may be more or less effective at different times following diagnosis or a cardiac event.

Who should deliver the intervention?

The participants of this study varied in their opinions as to who should deliver or manage a new CHD depression intervention, although no one suggested that a GP should lead. There was a majority opinion, however, that there is currently no suitable person within primary care, at least, not without training. It was felt important that the person delivering the intervention should be knowledgeable about and have experience of managing both CHD and depression.

The PNs were all experienced in managing the physical aspects of CHD, but their confidence and interest in dealing with psychological problems varied widely. This could be addressed through training. Nurse-led psychosocial interventions have been shown to be effective, including in heart disease.^{72,73} However, many nurses complained of a lack of time. A previous study⁴¹ has shown that it is possible to have a flexible attitude to time management in primary care in order to manage depression effectively. This was supported by data from GPs and a PN in one practice where the policy was to be flexible with time in order to address their patients' psychosocial needs. The observation from this study that PNs with 30-minute, as opposed to the more usual 15-minute, appointments often tended to be more willing to provide informal counselling to depressed CHD patients also supports this. If the new CHD depression intervention is to be delivered by PNs, it could be made attractive to them if it could be shown that it would save them time. This may be achieved by pointing out reports by PNs, gathered during this study, that they currently spend a lot of time delivering informal counselling despite being unsure that it is effective.

Finally, this study has identified that some primary care clinicians may be reluctant to raise the subject of depression with their CHD patients. In addition, several of the clinicians perceived that their patients were also unwilling to do this or to accept treatment. This may explain findings that depressed patients with comorbidity, including CHD, were less likely to be treated for depression.⁷⁴ In this study, one reason cited for this reluctance to discuss mood was fear of stigma, both in patients, who did not want to be stigmatised, and doctors, who did not want to create stigma. Stigma around mental health is well documented.⁷⁵ Some participants suggested that the use of screening questionnaires helped them to raise mental health issues in a non-threatening manner. This is supported by recent findings that patients liked their GPs using questionnaires as they saw them as an efficient and structured supplement to medical judgement and as evidence that the doctor was taking their problem seriously.⁶⁰

Other reasons for not addressing mood were lack of confidence or interest in treating mental health problems, prioritisation of physical health problems and a belief that 'nothing could be done' about the depression, which occurred mainly when depression was perceived to stem from social difficulties. These views suggest that, although they are very aware of the social difficulties experienced by their patients, some clinicians are still working with a biomedical model of health, where mental health and physical health problems are viewed as separate entities. This is despite the widespread acceptance of the biopsychosocial model⁷⁶ as a more useful explanatory model of health.⁷⁷

Adoption of the biopsychosocial model may empower clinicians to manage mental health problems that they see as social in origin. Care systems built around an understanding that physical and mental health are interlinked and occur in a social context may lead clinicians to explore management options other than those that are traditional within primary care, for instance local clubs to combat isolation and advice agencies. Some of our participants were aware that such facilities may be useful, but there did not appear to be any system for identifying local facilities or for matching them to their patients' needs. For this to work, such facilities must be available and accessible. This study shows that provision does vary within the limited geographical area of south London, but also that many clinicians are not fully aware of all the local facilities that are available to them. Any new intervention should aim to optimise use of existing facilities.

Therefore, as well as aiming to improve patient health, any new intervention for CHD depression should aim to increase clinicians' awareness of the inter-relationship between physical and psychological health, and the social context in which it occurs. It should also be aimed at increasing primary care clinicians' feelings of self-efficacy in managing complex psychological needs that may appear to be social in origin.

Conclusions

The study suggests that for many GPs and PNs, only depression that is severe and chronic is considered to need treatment in CHD. QOF screening questions are valued in detecting depression, but use of these is not routinely followed up with a more detailed questionnaire, such as the PHQ-9, which may be more accurate. Routine use of more detailed questionnaires, especially by PNs, many of who currently do not have access to these, may increase identification of CHD depression.

The GPs and PNs in this study felt that managing depression in CHD was worthwhile. To be accepted by clinicians and patients, a new intervention should have clear referral criteria and be local to the practice. The participants valued their clinical judgement and recognised the importance of patient choice in successful management; a new intervention should offer a range of treatment options that clinicians and patients can select together. These should include options for problems identified as exacerbating or causing depression in CHD, such as erectile dysfunction and being housebound. This study suggests that housebound patients currently may not receive adequate psychological care. Many clinicians felt that exercise is useful in managing CHD depression; there may be potential to develop this as a management option.

Depression in CHD may be exacerbated by, or may exacerbate, distress or depression associated with social problems. Potential exists, in CHD depression management, for greater use of existing local resources to combat problems common in CHD, such as social clubs for loneliness or agencies for financial or housing advice. However, clinicians vary in their perceived responsibility and ability to manage such problems. Some may need to be supported and empowered to manage problems that they consider social in origin.

Similarly, despite good evidence that cognitions are important predictors of response to chronic disease and that changing cognitions may improve health outcomes, GPs and PNs appear to vary in their understanding of this. A new CHD depression intervention should include education for clinicians concerning the role of cognitions such as illness perceptions, self-efficacy and motivation in chronic disease management.

Factors associated with depression in CHD may vary according to the time elapsed following receipt of a diagnosis or a cardiac event. Distress or depression immediately following diagnosis or an event may resolve spontaneously in many patients. An early intervention to manage unhelpful illness perceptions may reduce the number of patients whose distress or depression does not resolve. In patients whose depression is persistent, a more complex intervention may be needed to address adjustment problems or social issues which are exacerbating the mood problems.

Finally, this study suggests that there is currently no suitable professional within primary care to deliver a CHD depression intervention, at least not without training. Some nurses say that they would be willing to be trained to do this, but others would need persuasion owing to a lack of interest in or perceived responsibility to manage mental health problems. Given their current heavy workload, all PNs would need to be convinced that any new CHD depression intervention was effective and would have timesaving benefits. Time may be saved by reducing the time spent in informal counselling, which the PNs report to be time-consuming and of uncertain benefit.

Summary: what we learned from reviewing existing literature and conducting our own qualitative study

The findings of our metasynthesis of studies of primary care management of depression in general and our qualitative study of primary care management of depression comorbid with CHD were complementary. On balance, GPs and PNs expressed uncertainty in the management of depression, citing lack of time, training and available management options that are acceptable to patients. That these findings were similar for our metasynthesis and this qualitative study indicates that GPs and PNs have similar struggles when managing depression whether or not it is comorbid with CHD. Social problems, in both studies, were seen as important contributing factors, which should be addressed; our qualitative study indicated that these might be especially important in CHD patients who often come from low socioeconomic groups. However, GPs and PNs are uncertain in their role in and responsibility for addressing social problems and existing resources are underused; a finding from both our review and this qualitative study which highlights the need for a new intervention to help address this. Nurses' attitudes towards and confidence in managing depression varied enormously. This was a finding of both our review and qualitative study, and, as primary care patients with CHD commonly receive most of their care through nurse-led clinics, suggests that the development of interventions for depression in these patients should include sensitive consideration of nurses' views.

By asking clinicians, in our qualitative study, to consider depression comorbid with CHD, we not only confirmed that the findings of our review were relevant when managing people with CHD, but also identified issues that may be particularly important to people living with CHD. For instance, erectile dysfunction is a common problem that is not addressed routinely despite clinician awareness that this can contribute to depression and that if people with CHD become housebound, they are unlikely to receive any help for depression.

Strengths and limitations

Through the inclusion of only recent studies conducted in the UK, we ensured that our metasynthesis produced findings relevant to current practice within the NHS; findings may be less relevant to those wishing to develop interventions in other health-care systems. The aim of our review was to identify broad themes concerning depression management in order to inform our qualitative study focusing on managing depression when it is comorbid with CHD and hence we excluded studies focusing on specific aspects of the management of major depression such as antidepressant use. These more specific aspects of management were, however, addressed in our qualitative study focusing on their relevance to people with comorbid CHD. As is the case with all metasyntheses, we had to make decisions concerning which studies to include; we have detailed our methods clearly but others conducting the same review may have selected different studies. The findings of our review and qualitative study were, however, concordant, indicating that our choices were appropriate and that we produced robust findings to inform our intervention.

The findings of our metasynthesis were extremely useful in ensuring that our qualitative interviews were focused on known barriers and facilitators to managing depression in the UK; this information was essential in ensuring that our intervention would be feasible to deliver in primary care. However, we also used an iterative process of data collection and analysis so that new topics could be explored in subsequent interviews. For instance, the idea that depression in some people with CHD may be compounded by erectile dysfunction or by being housebound had not been identified in our review. Such findings emphasised the need for a future intervention to be personalised in order to address the varying needs of individuals. A potential weakness is that our participants were all practising within south-east London; however, we were careful to recruit from areas of contrasting deprivation and affluence in order to elicit a range of experiences.

It should also be noted that, as in the case of all qualitative research, it is possible that our positionality influenced our final findings. For instance, the UPBEAT-UK programme was funded to consider the 'problem' of depression comorbid with CHD and this informed our methodology. Had we conducted a study about the impact of illness on well-being and health as a resource for daily living, our findings may have been different.

Finally, since we conducted our study, guidelines for the management of depression with a chronic physical health problem have been issued;¹⁸ these may impact on attitudes and practice in the future.

Conclusion

Our systematic review of existing literature describing GPs' and PNs' experience of managing depression in UK primary care identified a range of barriers and facilitators to delivering care that need to be considered when designing future interventions for depression. We were then able to determine whether or not similar barriers and facilitators were experienced by GPs and PNs when managing depression in patients who also have CHD by conducting our own qualitative study. This work addressed a gap in the literature highlighted by our review and helped us to determine GPs' and PNs' views concerning what an intervention for people with sCHD and comorbid depression should consist of. By seeking clinicians' views directly, we were able to identify elements (such as the need for a flexible, personalised intervention which allowed clinicians to use both their clinical judgement and existing tools and resources) of a future intervention, which would make it not only effective (in terms of addressing care needs identified as unaddressed in these patients) but, importantly, feasible to deliver in current practice.

The following chapter describes how we also sought the views of patients with CHD and comorbid depression to inform our intervention. How this work was synthesised to develop an intervention to test is then detailed in *Chapter 4*.

Chapter 3 Perceptions of distress and depression in patients with symptomatic coronary heart disease: a qualitative study (work package 1)

Introduction

In the introductory chapter, we described how CHD and depression are both common health problems worldwide and are predicted to be the two top causes of global health burden and disability by 2020. We have described how depression has previously been associated with worse cardiac prognosis and an increased cardiac mortality. We described a need to better understand the relationship between the two disorders and a pressing global public health need to improve integrated primary care for people with both disorders.

Although the prevalence of depression in patients with CHD is high, little is known about how people with CHD and comorbid depression perceive these conditions and the relationship between them. Treatment trials for patients with CHD and depression have included antidepressant medication with some success in reducing mortality.^{78,79} However, it is currently unclear whether or not patients with CHD would opt for other interventions recommended by NICE for depression, such as supervised exercise, guided self-help, problem-solving, group or individual CBT or interpersonal therapy. It is also unclear whether or not NICE guidelines for depression need modification for patients with concurrent CHD and depression.

Before designing a new primary care-based intervention by nurses for patients with CHD and concurrent depression we undertook qualitative research to explore patients' perceptions of their depression in the context of CHD, their health-care preferences and own self-help strategies for coping with depression.

In this chapter we report on qualitative findings from a pilot study of five unstructured interviews with UPBEAT-UK cohort study patients with sCHD (chiefly chest pain) and symptoms of depression, as well as qualitative findings from a semistructured interview study with 30 UPBEAT-UK cohort study patients presenting with sCHD and symptoms of depression.

Aims

The study aimed to explore (1) primary care patients' perceptions of links between their physical condition and mental health; (2) their experiences of living with depression and CHD; and (3) their own self-help strategies and attitudes to current personalised care (PC) interventions for depression.

Methods

The sampling frame was the UPBEAT-UK cohort study database of primary care patients with CHD. At the time of recruitment (November 2008–January 2009) this numbered 376. On recruitment to the cohort, study participants were given the option of being interviewed in depth about their experiences of CHD and how this affected them emotionally. From participants who agreed to be contacted, we purposively sampled for positive scores on the PHQ-9,⁸⁰ which indicates symptoms of depression. We also sampled for maximum variation on sociodemographic factors: age, sex, ethnicity and occupational status.

At the time of sampling, 42 patients screened positive for symptoms of depression and of these, five were included in the pilot interview study. Of the remaining 37, one patient declined and three could not be contacted or had died. Of the remaining 33 patients, 30 were interviewed, at which point interviewing was stopped as data saturation had been reached.

We conducted five individual unstructured pilot interviews and 30 semistructured interviews. Topic guides were informed by the aims of the research, review of the literature, discussion with coauthors and findings from the pilot interview study. We audio-recorded all interviews and transcribed them verbatim following written informed consent. Transcribed interviews were entered into NVivo 8 qualitative software for analysis and data management.

All transcripts were analysed using a thematic approach⁸¹ involving a process of constant comparison between cases.⁸² Analysis began alongside data collection, with ideas from early analysis informing later data collection in an iterative process. Analysis of individual transcripts commenced with open coding grounded in the data. This generated an initial coding framework, which was added to and refined, with material regrouped and recoded as new data were gathered. Codes were gradually built into broader categories through comparison across transcripts and higher-level recurring themes were developed. Data were scrutinised for disconfirming and confirming views across the range of participants. Discrepancies were resolved by discussion at regular UPBEAT-UK research meetings to ensure consistency.

Pilot interview study

Study results

Participants

Participant characteristics are recorded in *Table 3*.

Participants were given pseudonyms to protect their anonymity.

Seven key themes were identified:

1. taking control and individual coping strategies
2. the significance of having heart problems
3. ambivalent attitudes to accessing PC mental health services
4. services participants would like for heart disease and depression
5. future orientation (having achievable hopes and dreams for the future)
6. the positives
7. contributory or causative factors for distress/depression.

TABLE 3 Participant characteristics

Age	Sex	Ethnicity	Occupational status
57–59 years	Two male	Three white British	One full-time employment
		One Afro-Caribbean	One disabled
	Two female	One South Asian	Three retired

Taking control and individual coping strategies

Analysis of pilot interviews revealed the ways in which patients tried to gain control of their health and emotional well-being and the individual coping strategies they used. These included:

- devising own fitness regime
- going to the gym
- studying health issues and alternative or complementary medicine
- meditating
- praying and being an active member of a religious community
- learning specific relaxation techniques based on yoga and Buddhist philosophy
- fishing and being in the natural environment (described as a yoga-like experience)
- being able to drive
- setting goals for exercise and pacing performance
- getting an allotment and growing vegetables
- volunteering at a hospital.

The following are illustrations of strategies used by participants: devising own fitness regime, going fishing and going to the gym. These examples not only illustrate the most cited strategies used but also individual differences in participant preferences for individual or group approaches to self-help.

Geoff described his fitness regime; he has a mini-gym in his sitting room and also goes fishing. He explained:

I've got equipment where I train, I've got the balls, I've got the weights, I've got a track that I run on, and I got legs . . . because of this operation, because I have got arthritis I got to strengthen my legs . . . and I got a thing to do my upper body. Yeah I train at least once per week.

When exercising and out walking, Geoff also wears a heart rate watch and he finds this source of 'biofeedback' helps him to pace and monitor his exercise, particularly when climbing hills. Geoff finds that being by the river, fishing and enjoying the natural environment a therapeutic experience in itself, he said:

Yeah, yeah, it's like a yoga, you can go into your own trance can't you, you can sit by the river and just imagine you're doing anything, it's like yoga.

Geoff had worked as a porter in the various Covent Garden markets for most of his life but since retiring he had built up a sizeable collection of books on alternative and complementary approaches to health. Geoff may have symptoms of depression, as detected by his PHQ score, but he is actively taking control of his health.

Another participant, June, talked about the 'psychosocial' benefits she gained from her regular trips to a gym where there was a special programme for heart disease patients:

. . . there is a group there [at the gym] and nine times out of ten we spend most of our time laughing!

This participant clearly enjoyed the fun she had with other people who had similar health problems and were trying to cope with the gym equipment and exercises through laughter.

The significance of having heart problems

For all five participants, having heart problems was not the health condition that concerned them the most. Three out of the five participants suffered from arthritis and this condition appeared to be causing more problems than heart disease owing to chronic pain and impaired mobility. One participant, June, was unable to work because of arthritis in her shoulder, arms, legs and ankles. She had already undergone five operations for arthritis.

Out of the five participants, Gurch seemed the most depressed or unhappy. Gentle probing about his heart problems (bypass surgery and a number of heart attacks) and how this had affected his feelings almost immediately led onto the topic that dominated the interview: his unhappy marriage and home life and his abuse of alcohol. The following exchange illustrates the problems Gurch had experienced:

Researcher: But how did it [heart bypass surgery] affect you emotionally, what did you think and what did you feel?

Gurch: At that time there are family problems.

Researcher: Did you have family problems?

Gurch: Yes family problems you know then I just take so much whisky you know drank you know.

Researcher: All right so I understand that you were saying that you had family problems and that was why you were drinking a lot.

Gurch: It was one of the causes you know, the family problem you know I don't know (. . .) my wife is but I do not know at that time you know, what are right what are wrong, anyhow it were due to my family quarrelling.

A little later in the interview he reflected that at the time of his heart bypass surgery, nearly 23 years ago, he was 'totally unhappy, just spending my time you know just passing my time'.

Like Gurch, four out of the five participants had experienced problems in their marital relationships that seemed to have affected them over a long period of time and caused them unhappiness, anxiety and depression. In comparison with their relationship issues, participants seemed almost blasé about their heart problems.

Ambivalence about accessing mental health services

The next theme explored participants' ambivalence about accessing mental health services through their GP and these included:

- cultural perceptions of depression can act as barrier to accessing help, for example in South Asian and Sikh communities
- not knowing the meaning of 'depression'
- suffering seen as Karmic – in the hands of God
- cannot talk to anyone in community (stigma?)
- fearing negative perceptions of GPs as always 'moaning and groaning' (this idea is reinforced when doctor praises client for not moaning)
- discomfort in talking about emotional issues
- low self-esteem and a sense that their problems are not worthy of attention
- the perception that their health is relatively good and that there are people in far worse situations
- some people do not want to go down that path because it frightens them.

Excerpts from interviews with June and Ivy illustrated how health stoicism and fear of being viewed negatively by their GP acted as an inhibitor to accessing primary care health services. Although June suffered from asthma, arthritis, heart disease and possible depression she seemed reluctant to visit her GP other than for her regular 2-monthly check-ups. June explained '... there are some times when you are thinking to yourself that there are people a lot worse off than you!'.

Ivy had also adopted this approach – even though she was 79 years old and had heart disease, arthritis, balance problems and symptoms of depression. She explained:

Ivy: To be honest, I hardly go near them [GP surgeries] . . . I mean they have got enough to do when they have got a whole lot of patients who are worse off than I am.

Researcher: OK so do you think of yourself as being in quite good health?

Ivy: Yeah.

Researcher: You think 'I'm OK I'm much better off than some people'?

Ivy: Yeah, yeah.

Researcher: And does that make you feel better?

Ivy: Sometimes it does.

Although the strategies of stoicism and 'counting your blessings' that Ivy used can have some positive benefits (putting problems into perspective to combat feelings of anxiety about health) it can also act as an inhibitor to accessing health care.

June was concerned that her GP might perceive her negatively by making more frequent visits to the surgery. June explained:

June: I don't want to come in too often!

Researcher: Too often?

June: Even though they say they don't get fed up, you don't want them to get fed up, you know?

In relation to depression, a study by Priest *et al.*⁸³ found that stigma was still associated with depression, and patients felt ambivalent about consulting a family doctor. Some feared the GP would make negative evaluations of them or would be irritated or annoyed. With this in mind, June might be similarly reluctant to disclose her feelings of depression to her GP.

Services participants would like for heart disease and depression

In relation to the services participants would like for heart disease and depression, participants seemed more interested and comfortable in talking about services they would like for heart disease. The following suggestions were made:

- more frequent (physical) check-ups at the GP surgery with specialist nurse and improved feedback
- being able to request a check-up when needed
- access to a gym with specialist cardiac trainer for attention, guidance and reassurance
- the promotion of wrist heart rate monitors
- some people were interested in having counselling
- one participant had counselling and found it helpful.

Three out of the five participants had used a gym as part of their aftercare but only one participant, June, seemed to have attended sessions that were designed for people with heart problems. The other participants attended general fitness centres where they were assessed by a trainer and then given a set of exercises and left to get on with these on their own. These three participants all felt that a dedicated session would be preferable, particularly in the period immediately after their coronary incident when they

needed the most reassurance about symptoms and safety while exercising. June's experience of going to a dedicated gym session was an enjoyable one because there were a group of people 'in the same boat' and they had a good laugh. She also felt safe and reassured by the trainer when she had some cardiac symptoms. Even though this kind of CR might not be considered a psychological intervention, in the strictest sense, it may have some positive outcomes for patients suffering from mild depression and may also help to prevent a 'cardiac invalid' mind set.

Only two out of the five participants had received help for depression from their GP. None of the participants had received antidepressant medication, June had received information and Ivy had attended counselling sessions. Geoff had been offered group therapy but did not want to attend. Generally participants seemed cautiously positive about the idea of receiving one-to-one counselling while less positive about group therapy.

Future orientation (having achievable hopes and dreams for the future)

When asked if there was anything the participants enjoyed or were looking forward to doing with their lives, the following topics were discussed:

- planning for a holiday with a friend
- gaining skills needed for a new way of life
- planning to retire and live abroad
- wanting to learn how to use a laptop
- volunteering at a hospital.

In a critical literature review of the relevance of hope in the trajectory of heart failure illness, Davidson *et al.*⁸⁴ explained:

... hope ... defend[s] against despair by focusing on the future. Expectations can be directed toward relief from a difficult situation. To achieve this relief, people must have a sense of control over their environment and feel that they are capable of making decisions that alter their life circumstances.

In relation to hope, four out of the five participants gave examples of achievable personal goals. When talking about their personal dreams, participants looked relaxed and animated, and their body language changed. Even the unhappiest participant, Gurch, seemed a different person when talking about his activities as a volunteer with Parkinson disease patients at a London hospital. Besides a lot of other benefits, being a volunteer had given Gurch some future orientation. Gurch explains how this has affected him as follows:

Gurch: *It makes me feel good, when I help a person and I can see that they are suffering like that you know and I help ladies and gentlemen who are suffering from this disease how to do step by step.*

Researcher: *You are looking a lot happier while you are talking to me about doing the volunteering you look quite happy.*

Gurch: *Yes I am happy.*

Another participant, James, talked about his hopes and dreams for the future as follows:

... we've got friends in Portugal that are living in a very beautiful kind of place and it is very nice to go and visit them and I think 'this will do me fine' nothing grand, just something with a bit of land. Errr, yeah and this is why I am doing the allotment because I need to know that I can do it, if I want to.

James was close to retirement age and was seriously considering starting a new life abroad. He was taking some practical steps in preparation for his goal of having some land of his own to cultivate.

Similarly, June talked about her wish to go travelling as follows:

June: What I want to do at the moment is to go travelling and I can't at the moment, I want to go away for a holiday but I will have to wait. That is what I want; I really, really want to go away.

June and a friend were hoping to go to Jamaica in a year's time, health permitting.

Maintaining hope and encouraging a future orientation may be important factors to consider in devising interventions for patients with CHD and depression. Patients with CHD may need some help in either finding a future goal or in taking practical steps to achieve something they want to do.

The positives

Although all five participants had positive scores for the PHQ-2⁸⁰ and had suffered from periods of 'unhappiness' over the course of their lives, participants spoke about the positive aspects of their lives, their friendships, interests, hopes and dreams or about how they had successfully tackled personal problems, such as alcohol abuse. Of the five participants:

- four had a close friend, group of friends and contact with family members
- four mentioned things that they enjoyed doing
- one participant had used his experience of heart disease as an opportunity for personal growth and improved care of self
- the unhappiest participant was trying to improve his situation by volunteering and by trying to understand his unhappy relationship
- two participants with alcohol problems had managed to either abstain or moderate their drinking behaviour.

One participant, James, thought that his heart disease had given him the opportunity for change and personal growth. James explained as follows:

I started the yoga and the Buddhism and a couple of the meditation techniques. It did change me quite a lot and I was quite happy about that change . . . I used to be somebody I didn't like very much and now I am somebody who is OK, as far as I'm concerned. I used to treat people very badly and I used to argue about anything and would drink a lot and I have stopped doing a lot of those things really.

In the excerpt above James explained how having a heart attack had been a catalyst for change in his life. He had also changed his diet and lost 5 stone in weight.

Participants' perceptions of what caused or contributed to feelings of distress and depression

Participants talked about the issues that they felt had contributed to or caused their depression and these included fear of dying, boredom, unhappy relationships, chronic pain and disability, low self-confidence, alcohol abuse, being bullied and being bereaved.

In the interview with Geoff, dying and fear of dying was a topic touched on in different ways. Geoff was understandably scared when he realised he was about to undergo open-heart surgery. Geoff also referred to his sense of frustration with other heart disease sufferers who were becoming 'cardiac invalids' because of their fear of dying and he gave examples of friends who had suddenly died from a heart attack, reminding him of his own mortality.

The following extract describes Geoff's reaction when he first realised he was going to have a heart operation.

Geoff: So I went up the hospital earlier about me stomach he looked at me diagrams and me sheets and all that and he said 'do you want us to do this one first' and I thought 'what one is that?' He said sort out yer valves in your artery and so I said Oh . . . !

Researcher: So that was news to you was it?

Geoff: Scary and all. So I said 'OK then' he said 'do you want to know what the chances are of dying?' and he said 'six to one' so I said 'all right then.' So he said it will be a little while before we get a spare bed so I come home here and then I got a phone call to say could you come in. So that's when the scary part went in!

Geoff's interview provided examples of how the reality of dying had affected and distressed him. Indeed, since his operation some years ago he had become very interested in health matters and had devised his own fitness regime that involved monitoring his heart rate, using a wrist monitor. One could speculate that Geoff's anxieties had been channelled into monitoring his heart rate, as the following extracts might suggest:

Researcher: You go fishing yeah and what does going fishing do for you? Why do you prefer going fishing to group therapy?

Geoff: Because I can train. I got a hill like that (tilts hand) and I go up the hill but I don't do that straight away but that's a little bit of training that is getting me heart pumping I do it and when I reach the 120 heart murmurs I stop because I have to watch . . . that's a good idea if you can get them free, a heart watch so if people are training and have just had open heart surgery and the doctor said 'if you want your heart rate to be 120 you should look at your watch and if it says 120 and then I stop, stop going up the hill work it to about 112 and then I will carry on back up the hill, don't forget I've got all me fishing gear with me and a barra [barrow].

And later in the interview he continued . . .

So when I go fishing there is a hill and it is a hill, but I want to work me heart so going up this hill is errh when I get to 120 . . . I done 130 actually and then I did stop. I wasn't out of breath but I just thought 'well that's too much for me' so I went and I looked at me clock and it was 130 and I thought 'that's quite good', it went down to 112 and when it goes down to 112 the heart is (makes pumping sounds) just nicely beating . . .

Although Geoff was doing something positive about his health, his need for reassurance through biofeedback could be a manifestation of the anxiety he was experiencing. Geoff was not interested in attending group therapy sessions because he felt that listening to everyone's symptoms of heart disease would make him worried for them (or perhaps remind him of his own health issues).

Discussion

The themes explored in this pilot study have revealed more similarities than differences among five participants who were purposively sampled for contrasting demographic backgrounds.

The participants did not want to be perceived as 'moaning and groaning' in relation to accessing health care and were mostly uncomfortable in talking about their feelings and ambivalent about accessing mental health services.

Although all of the participants had experienced unhappiness in their lives (mainly owing to relationship problems) they were all still trying to do the best they could and seemed to prefer taking their own courses of action to improve their lives, thereby preserving a sense of agency, control and future orientation.

For all of the participants, having heart disease and the symptoms of heart disease did not seem to be their main health concern. In contrast, chronic pain and impaired mobility caused by conditions such as arthritis seemed to affect participants the most.

Most participants would like to be able to attend dedicated gym sessions for people with heart problems so that they feel safe and supported. As dedicated sessions provide an opportunity for social interaction with other people with heart problems there is also an opportunity to make these fun and enjoyable and thereby emotionally therapeutic.

The main difference between the responses of the participants was evident with one participant, James, who seemed more comfortable about introspecting and talking about his feelings. James occupied the highest occupational status of the five participants and this difference in socioeconomic status/social class might indicate that he has access to and is familiar with psychological discourses, whereas the other four participants appeared to refer to ideas of stoicism in preference to introspection. There may well be issues of social class influencing the importance patients place on their feelings and whether or not these are appropriate and safe topics to discuss, either with a researcher or a health-care professional.

How the pilot study informed the main interview study

For the pilot study, an unfocused interview approach was adopted to allow participants to raise issues that were salient to them around the topic of CHD and depression. Findings from the pilot interviews and UPBEAT-UK literature reviews were used to inform the topic guide for the main interview study. This approach allowed us to balance topics identified in academic literature with patient-centred perspectives.

The researcher commenced the interviews by asking the following question: 'So, if you wouldn't mind just starting by telling me about when you first knew that you had some problems with your heart.' Participants responded to this request by recounting personal accounts of their lives in the context of CHD and depression. This narrative approach worked well in the pilot study; it provided an opportunity to assess how participants perceived the connections between their physical, social and emotional worlds, in the context of illness. For this reason a narrative-based topic guide was developed for use in the main interview study.

Main interview study

Study results

RS interviewed 30 patients with CHD and symptoms of depression. The main findings from this study have been published in an open access journal paper by Simmonds *et al.*⁸⁵

The interviews were conducted using a narrative approach guided by topics informed by findings from the pilot interview study.

While recounting their stories of CHD and depression the following topics were explored:

1. participants' perceptions of the relationship between their physical and mental health
2. participants' experiences of living with depression
3. participants' own self-help strategies for coping with depression
4. participants' views and experiences of primary care interventions for depression
5. participants' ideas for primary care-based interventions for depression that they would like to be made available.

Summary of results

Loss was a theme that underpinned all of the interviews in this study, as seen in *Figure 2*. Losses included interpersonal and health factors.⁸⁵

In relation to health, participants experienced a sense of loss that also impacted on feelings of agency and being in control of their lives. Loss of good health through CHD had impacted on employment status and financial security for some participants. Participants also communicated a loss of control in relation to their bodies, sense of gender identity and the ageing processes in general. Some participants tried to reclaim and exercise control by resisting the 'medicalisation' of their lives, particularly in relation to treatment interventions for depression, such as antidepressants. Participants also exercised control by developing their own self-help strategies in relation to depression. The kind of self-help activities participants preferred fell roughly into two types: (1) social and interpersonal, typically involving group activities and (2) lone activities, such as fishing or meditation.

Participants varied in the extent to which they attributed feelings of depression to their physical condition. Three levels of association between mental states and CHD were identified: (1) direct links made between CHD and depression; (2) indirect links between CHD and depression; and (3) weak links between CHD and depression. The three levels of association are summarised as follows.

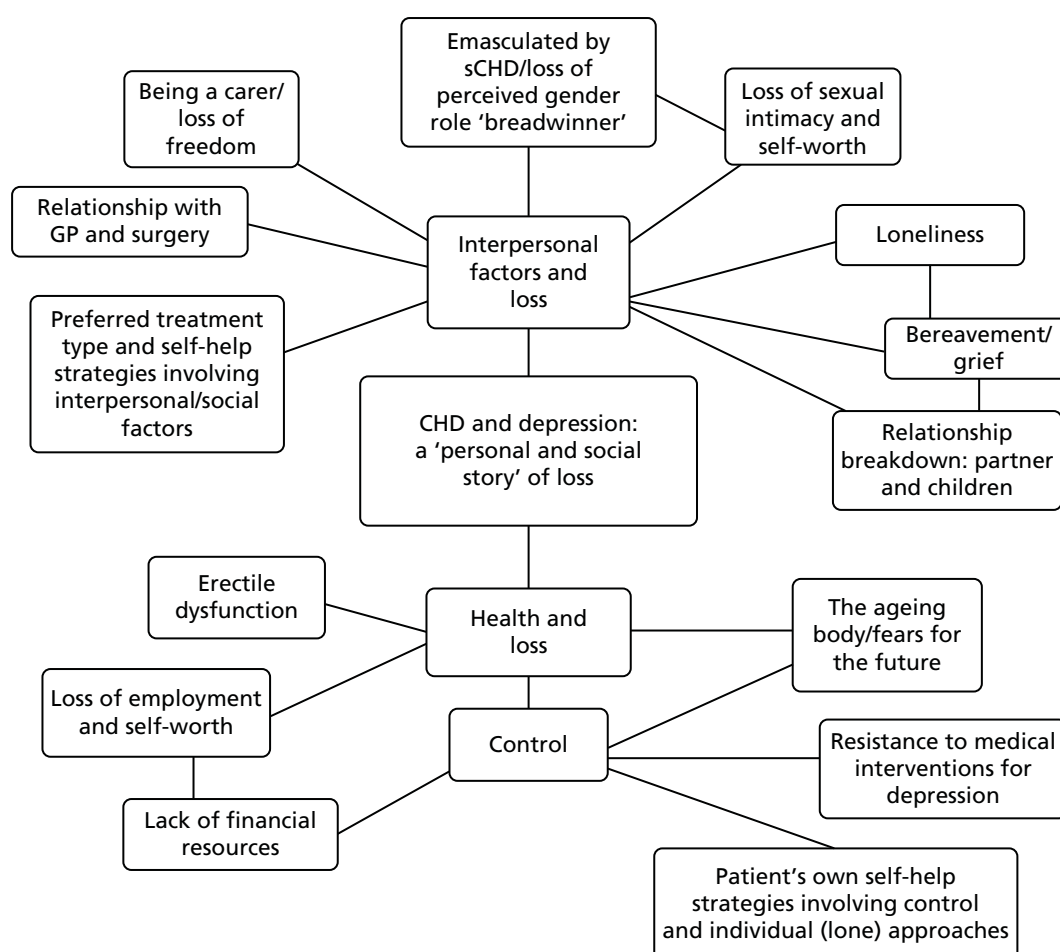

FIGURE 2 Interpretative diagram of themes relating to participants' perceptions of sCHD and distress/depression.

Direct links made between coronary heart disease and depression

Of the 30 participants interviewed, 63% (19 participants) were male. Nearly half of these male participants (30% of the sample) reported feeling depressed, very depressed or suicidal after having a heart attack and explicitly stated a link between feeling depressed and having CHD.

The way men described their feelings was closely connected to the loss of perceived manliness (emasculation) and gender roles, which included loss of ability to work, erectile dysfunction and generally feeling 'useless'.

Indirect links made between coronary heart disease and depression

Fewer direct links were made between CHD and depression by participants who reported a history of negative life events.

Factors contributing to or causing depression in this category were underpinned by feelings of interpersonal loss. The main issues that participants reported as 'getting them down the most' were:

- marriage and partnership breakdown/unhappiness, problems with access to children after marital breakdown, loss of home/homelessness
- bereavement issues through the death of a child, partner, parents and friends
- being a full-time carer for wife, not having any support or respite and not being able to visit children in America.

Although partnership breakdown was reported as being a major, long-term, stressful experience by male and female participants alike, more male participants talked about the added stress of either losing touch or being denied access to their children. Destructive family politics were mentioned by a number of participants, both male and female, and these corrosive situations had caused a great deal of stress.

For participants who had talked about marital or relationship breakdown the breakdown had preceded CHD and participants partly attributed their feelings of distress or depression to this experience and partly to their physical condition. Experiencing stressful life events was seen more as a factor that caused participants' heart disease rather than heart disease causing them to feel depressed.⁸⁶

Participants experienced bereavement as a severe loss and the source of ongoing distress. Some participants believed that there was a causal link between experiencing grief and heart disease. Parkes *et al.*⁸⁷ argued that the association between heart disease and bereavement is one that cuts across social class difference. Patients with CHD may need particular help in the case of bereavement.

One participant was a full-time carer for his wife, who was incapacitated through rheumatoid arthritis. Although this participant was in his eighties and had suffered a heart attack, he did all the housework, washing, cooking, shopping and personal care for this wife.

This participant reported feeling depressed about being trapped in the daily grind of being a carer and not being able to visit his children in America. His wife refused any respite care and her family were unsupportive. The loss that this participant was experiencing centred round a loss of freedom, which included the freedom to visit his children in America.

Weak links made between coronary heart disease and depression

A number of participants were coping with CHD and comorbid conditions including: asthma, psoriasis, chronic obstructive pulmonary disease (COPD), arthritis, diabetes, thrombosis, sarcoidosis, stroke, hearing loss, poor eyesight, diabetic blindness, memory loss, prostate problems, kidney problems, paroxysmal positional vertigo, morbid obesity, underactive thyroid and restless leg syndrome. Chronic painful conditions limited mobility and interfered with the daily activities of participants.

Conditions that caused pain, such as arthritis, seemed to distress participants the most. As there are no 'cures' for some health conditions participants were faced with a seemingly never-ending illness trajectory. These factors, coupled with the realities of ageing, made the future seem bleak for some participants. Links made between depression and CHD were weaker in participants coping with other painful health conditions. Participants with comorbidities seemed more depressed and attributed low mood to physical conditions that were painful and disabling, such as arthritis.

NHS interventions and services participants found helpful or unhelpful

Talking therapies

Participants seemed to prefer NHS services for CHD and depression that included either or both of the following: interpersonal talking approaches and the opportunity for social interaction and support. Services that had been offered to patients and were considered helpful included: CR, information and self-help, counselling, referral to a psychiatrist or therapist and supervised exercise.

Although a few participants had received a counselling therapy for depression, there appeared to be some lack of provision for counselling services in primary care. Other problematic issues raised in connection with counselling were: continuity of care/therapeutic alliance, service availability, effective signposting, crisis prevention and waiting lists.

Psychiatric services

One male participant who had been severely depressed post cardiac surgery was very appreciative of the help that he received from two psychiatrists. However, it was the talking part of the psychiatric support that he found most helpful, particularly in expressing his feelings and in communicating these to his wife. This participant felt that his marriage had become stronger because of this therapeutic approach.

A number of participants had attended a 6-week CR programme post MI. Everyone who attended CR found it a helpful and positive experience. Participants found CR programmes to be useful and enjoyable for the following reasons:

- Mastery: patients taught to monitor their pulse rates, improve diet and lifestyles, and take back control of their bodies.
- Confidence: supervised exercise programme built confidence – patients felt safe and reassured about any physical sensations they were experiencing.
- Social support: patients enjoyed a group approach and supported each other.

As found in the pilot interview study, most participants in this study reported wanting to attend a similar supervised programme of exercise for patients with CHD rather than attending a normal fitness centre, where there may be a lack of supervision or group support.

Participants' own coping strategies

Most participants had developed coping and self-management strategies to help themselves when they were 'having a down day' and these included:

- Self-talk and thinking strategies: counsels self, counting one's blessings, setting mini-goals and pacing progress, visualisation techniques (taught by therapist).
- Meditation and yoga: a number of participants used meditation and yoga techniques for relaxation, to calm the mind and alleviate physical symptoms.
- Religious practices/spiritual beliefs: provides social support, calming effect of praying and being in place of worship.
- Exercise and hobbies: swimming, walking, fishing, lawn bowling, going to gym, Tai Chi.
- Creative expression: writing poetry, listening to music.
- Displacement activities: keeping busy, finding something to do.

Some of these strategies, such as goal-setting, self-talk/thinking strategies, and meditation and yoga could be developed in a primary care approach to treating concurrent CHD and depression.

Exercise

Exercise was a strategy used by participants to improve physical fitness, elevate mood and provide opportunities for social interaction. The kinds of physical activities mentioned were walking, swimming, Tai Chi, grass bowling, fishing and going to a gym. For some participants exercising also offered the opportunity to socialise with a friend and share experiences with family members.

Engaging in physical activities, hobbies and sports could be encouraged in primary care by identifying and addressing any barriers to access and through helping the patient to set goals, pace themselves and by monitoring and encouraging their progress.

NHS services for depression that participants did not find helpful

Antidepressants

Overall, participants were not enthusiastic about antidepressant medication for the following reasons: did not want antidepressants on medical record (stigmatising), incompatibility issues with other medications and unpleasant side effects.

Discussion

Most participants in this study had suffered heart attack(s) and other health/personal traumas that had impacted on every area of their lives. The losses experienced by participants were complex and multiple. For this reason the association participants made between CHD and depression varied substantially.

Male participants in the study made the strongest links between their physical state and mental health. Charmaz⁸⁸ (p. 268) observed 'illness can reduce a man's status in masculine hierarchies, shift his power relations with women and raise his self-doubt about masculinity'. These observations were reflected in our study of men who felt emasculated by CHD. Men who suffer serious cardiac disease may need specific therapeutic support to help them find new 'scripts' through which they can perform positive masculine identities.

Participants who had suffered losses in their personal relationships through divorce and bereavement made weaker causal links between CHD and depression. These participants attributed depression mainly to the unhappiness and upheaval they had experienced in their lives. Together with patients who had multiple health conditions, these participants felt that they needed someone to talk to, who would get to know them, rather than take antidepressant medications. Patients who have lost a partner through death or divorce might find the experience of ageing and ill health a lonely process. These participants do not want to 'burden' their children with their concerns and they are reluctant to talk to their GP because they generally do not want to be perceived as 'moaning and groaning'. Older CHD patients, living alone, may be more susceptible to depression if they lack an intimate confidante and someone they can share age-related anxieties with.

The theme of resistance underpinning reasons participants gave for not wanting to take antidepressants may be reflecting one way in which patients can reclaim some control. These patients may have been demonstrating resistance to the medicalisation of their lives and perhaps the resulting feelings of disempowerment this engendered. As a number of participants felt that their lives were already dominated by 'taking pills' perhaps they felt they *could* say 'no' to antidepressants, in contrast to the rest of their medication, which was probably essential to the functioning of their hearts. A diagnosis for depression as a 'mental illness' is a culturally powerful label that can have serious implications for how a person is perceived. Resisting antidepressants could be a way of resisting the meaning given to 'depression' via medical records and biomedical discourse.^{89–92}

Barriers to accessing care provided by GPs, such as an overly bureaucratic GP appointment system, a lack of patient privacy when upset and a lack of continuity of care can affect the quality of care for patients with mild to moderate depression.⁹³ Continuity of care, that allows the patient to develop a relationship over time with one GP, might also have the benefit of improving facilitation of conversations about emotions and feelings for patients who are distressed or depressed. Privacy and continuity of care may be important elements to consider when designing a primary care intervention for CHD and depression.

From care currently provided by the NHS for patients with CHD, CR courses and appropriately supervised exercise were rated highly by participants. However, the fact that participants enjoyed CR may not equate with a significant improvement in their depressive symptoms. A longitudinal study on the effect of CR on depressive symptomatology⁹⁴ concluded that exercise itself is not effective in alleviating depression and that CR programmes should provide specific screening and treatment for depression. Doing something enjoyable or useful is important to most people and perhaps this should be seen as just *one* important ingredient in a holistic approach to improving mental health rather than a treatment for depression per se.

Although a theme of 'loss' underpins participants' accounts of CHD and depression, this does not mean that participants' lives were totally devoid of happiness and pleasure. Participants talked about enjoying rewarding relationships with grandchildren, going on holidays and day trips, doing voluntary work and in self-development. Despite having symptoms of distress/depression, most participants had hopes and dreams for the future, some of which could be achieved through support in goal-setting and realistic pacing. A primary care intervention that includes a mentoring approach, as part of a stepped care model for treating depression, could help patients identify and achieve some of their goals while enhancing a sense of self-determination and control over their lives. *Table 4* summarises participants' ideas and preferences for interventions that could be delivered in primary care.

TABLE 4 Summary table of participant ideas/preferences for primary care interventions for CHD and depression

Type of activity	Translation to a primary care intervention	Similar approaches that can be adapted
Group-based exercise	Ongoing supervised exercise for people with sCHD: to achieve a sense of mastery, increased confidence and an opportunity for social support	Similar to CR programmes but ongoing
Individual approaches to exercise and other lone activities/interests of patient's choice	One to one with a PN to identify realistic goals Support in pacing and achieving goals Empowering patients Improving sense of control and self-confidence	Mentoring approach
Having someone to talk to who knows them – when they need it (within reason) – over an extended period of time	PN with CBT training Clinician continuity important Dealing with issues of loneliness by helping patient to make supportive social links in the community	Similar to CBT or solution-based approaches to counselling, but less formal/medicalised and with more flexible time frames. Privacy is also important

How findings from the interview studies informed the pilot intervention

A clear finding from the patient interview studies was that (1) participants were experiencing a range of social, physical and gender identity (erectile dysfunction) losses; (2) some participants preferred to do things on their own, whereas others preferred group activities; (3) most participants had hopes and dreams for the future or enjoyed some aspect of their lives; (4) participants felt disempowered by ill health and the medicalisation of their lives; (5) participants preferred therapeutic treatment approaches for depression; (6) participants were not enthusiastic about antidepressant medication; and (7) loneliness was a problem for a number of participants.

Given the diverse needs of the sample (older people with chronic health conditions who feel lonely, men who felt emasculated and/or want to work again and participants who had experienced a number of adverse life events) an intervention for patients with CHD and depression may need to adopt an individual approach that can accommodate the specific sociocultural and personal needs of patients. A holistic, case management/mentoring approach to depression in CHD could help patients to feel more empowered and in control of their lives, especially if they are supported to achieve personal and health goals.

While conducting the patient interview study, interim findings, participant suggestions and final conclusions were discussed iteratively with the UPBEAT-UK team. The final design of a primary care, nurse-led complex intervention was informed by both the GP and PN (see *Chapter 2*), and patient qualitative studies together with the UPBEAT-UK literature reviews.

Plans for the content and structure of a nurse-led complex intervention were discussed in-depth with patients (suffering from sCHD and depression) during a series of two focus groups. Adjustments to the design and content of the intervention were made according to recommendations from the focus groups.

Ethical approval

Bexley and Greenwich Ethics Committee gave ethical permission for the study (reference 07/H0809/38), and approval was obtained from NHS trust research governance offices in south-east and south-west London. The researcher (RS) consented the participants.

Chapter 4 Development and testing of an intervention for primary care patients with symptomatic coronary heart disease and depressive symptoms (work package 2)

Plan

The previous chapters detail how we gathered the views of patients, GPs and PNs as well as findings from published studies concerning requirements and preferences for a future intervention for people with sCHD and comorbid depressive symptoms. In this work package of the UPBEAT-UK programme, our aim was to develop and evaluate an intervention that would be feasible to deliver in UK primary care.

We conducted an iterative evidence review and synthesised data from previous work packages to develop the intervention, which we then modified informed by findings of a focus group study with people with sCHD and depressive symptoms and further literature review.

We then conducted an exploratory randomised controlled study to examine the acceptability, feasibility and potential costs of the new intervention, and to test the methods for a definitive trial.

Developing the intervention

Barley *et al.*² published a full account of the process that we used to develop the intervention in an open access journal in 2012. The key steps of the process, which followed MRC guidelines for developing complex interventions,³⁰ are summarised here. This process is also depicted in *Figure 3*.

FIGURE 3 The UPBEAT-UK study intervention development stages. Reproduced from Barley *et al.*² © 2012 Barley *et al.*; licensee BioMed Central Ltd. Phase 1: gathering evidence

This phase included the qualitative studies of patients and primary care clinicians, and the metasynthesis of published literature detailed in *Chapters 2 and 3*. Essentially, all three studies led to the conclusion that the needs of patients with CHD and depression are diverse and include psychosocial problems involving interpersonal and health/control losses that primary care staff are uncertain how to manage.

Phase 2: synthesis of findings from previous work packages and iterative literature review

Multidisciplinary team discussions involving GPs, psychiatrists, psychologists, nurses and a cardiologist, of our earlier studies led to agreement that the UPBEAT-UK intervention should:

- improve depression, quality of life and cardiac outcomes in patients with CHD
- help patients and clinicians to manage an individualised range of problems, including social problems
- be nurse-led and feasible for delivery in primary care.

These conclusions were used to guide literature searches focused on identifying high-quality systematic reviews and evidence-based guidelines: we searched the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effectiveness and the NICE website. We also looked for evidence published subsequently to the reviews and guidelines using MEDLINE, EMBASE and PsycINFO. Findings from the evidence reviews were discussed and used to support choices for the intervention content. This is detailed in *Table 5* (first published in our RCT development paper).²

We discussed the meaning of these findings in the context of UK primary care, where an established component of chronic disease management is the provision of self-management support; this means enabling patients to take better care of themselves, for instance by providing information and helping them to change unhealthy behaviours.

Two important factors for behaviour change are known to be belief in the importance of an outcome and belief in capacity to succeed (self-efficacy).¹⁰⁵ This suggested to us that instead of focusing on generic CHD or depression risk factors, the new intervention should enable patients to specify their own goals, for instance stopping smoking or increasing social contact, so that work is directed towards outcomes important to patients.

Informed by our evidence review a 'toolkit' of behaviour change skills and existing local resources was developed to facilitate nurses, acting as case managers, to help the patient to increase their self-efficacy and achieve their desired outcomes.

The intervention we developed therefore was a PN-led PC intervention. It comprises the following:

Personalised care planning: the nurse acting as case manager conducts a standardised biopsychosocial assessment (including physical and mental health, difficulties with current treatment regimens, problems with daily activities and social problems) face to face with the patient either at the patient's GP surgery or at their home, according to patient preference. Patients are helped to identify up to three problems that they consider contribute to their depression and which they most want to address. The nurse case managers, as applicable, provide information, signpost patients to existing resources (e.g. leisure centres, social clubs, IAPT services) and use evidence-based behaviour change techniques to help patients set and achieve goals. The underlying intention of the intervention is to increase the patient's self-efficacy to achieve their desired goals (as opposed to goals determined by others such as symptom management or reduction of cardiac risk factors, a primary aim of many previous collaborative care projects). Details of the assessment and action plan are recorded in a 'personalised health plan', which the patient holds.

TABLE 5 Iterative evidence review to guide development of an empirically based intervention to improve mood and cardiac outcomes in patients with CHD

Intervention should	Findings	Conclusions in relation to new intervention
Improve depression, quality of life and cardiac outcomes in patients with CHD	<p>NICE guidelines¹⁸ for depression with a chronic physical health problem recommend a stepped care model involving psychological therapy and/or pharmacotherapy</p> <p>Two Cochrane reviews^{95,96} identify a range of psychological and pharmacological interventions; there is insufficient evidence to determine which elements are beneficial. No effect found on cardiac outcomes</p> <p>A well-conducted trial in the USA¹² found that collaborative care improved depression and disease control in patients with CHD and/or diabetes</p>	<p>Collaborative care is intensive; our empirical work suggested only a minimal intervention would be feasible</p> <p>A key ingredient of collaborative care is 'case management' (CM):⁹⁷ a health worker follows up patients, assesses adherence, monitors progress, takes action when treatment is unsuccessful and delivers psychological support as part of a stepped care approach.²⁵ This is a central aspect of the UK long-term conditions strategy⁹⁸ so it is familiar to PNs</p> <p>CM allows PC but the processes by which change is expected to occur should be specified</p>
Help patients and clinicians to manage an individualised range of problems, including social problems	<p>The CHD and depression association is likely to be explained largely by behaviour.^{99,100} Behaviour change interventions for risk behaviours for CHD and depression have been delivered in primary care and shown benefit for smoking¹⁰¹ and alcohol intake.¹⁰² Not known if they are helpful for patients with CHD and depression</p> <p>Current UK policy¹⁰³ promotes liaison between professionals and utilisation of existing resources to tackle depression and adverse health behaviours</p>	<p>Training in specific behaviour change techniques and identification of existing local resources, such as social clubs, advice agencies and therapy services, would provide PNs with a 'toolkit' of resources that they could tailor according to patient need and preference</p> <p>Specification of interventions used will inform implementation and evaluation of the intervention</p>
Be nurse-led and feasible for primary care	<p>Case managers are often nurses, but studies lack details concerning implementation and process¹⁰⁴</p> <p>Evidence-based behaviour change interventions, such as goal-setting and action-planning, have been identified for use in primary care⁶⁴</p>	<p>Pilot work should be undertaken to understand which aspects of case management are effective in CHD patients with depression and which outcomes should be targeted</p>

Follow-up care: follow-up interviews to determine progress and/or set new goals are conducted via telephone to conserve nurse time. This is initially weekly and then the frequency of contact is agreed between the patient and nurse case manager. Calls are planned to last 15 minutes.

The intervention process is detailed in *Figures 4* and *5* (first published in our RCT development paper).²

1. Introduction

- Introduce yourself and explain the principles of case management

Materials: patient information leaflet

2. Conducting the assessment

- Assess how the patient's health is impacting on their life using the standardised assessment form

Materials: patient assessment document (for case manager)

3. Devising the personal health plan

- Record problems, professionals currently involved, actions to take
- Agree and set review date for each problem

Materials: personalised health plan

4. Goal-setting (if required by the patient)

- Help the patient to identify a problem to address. Use goal-setting to help them 'break down' the problem into manageable parts
- Introduce personalised health plan; patient to record up to three goals

Materials: personalised health plan, goal-setting information leaflet

4. Action-planning (if required by the patient)

- Help the patient to plan how to achieve each goal
- Patient to record; what they will do, how they will do it, where they will do it, when they will do it and with whom they will do it

Materials: personalised health plan

5. Providing information

- Provide individualised self-management resources

Materials: Lists of self-management resources

6. Building self-efficacy

- Ensure patient feels confident that they can achieve their goals
- Discuss barriers to success and ways to overcome. Patient to record reasons to expect success

7. Deciding a review date

- Record preferred contact details and date for review

8. Encouraging self monitoring

- Patient to record successes and difficulties in pursuing goals

9. Confirming confidentiality

- Increase trust by signing the confidentiality agreement

Phase 3: modelling

Having developed the intervention, and following MRC guidance,³⁰ we now wanted to explore its acceptability among people with sCHD and depressive symptoms. Using maximum variation sampling to select patients varying by sex, age, ethnicity and borough of residence, we invited participants of the UPBEAT-UK cohort study to attend two focus groups.

In a short presentation, two researchers (RS and Zoe Fortune) explained the proposed intervention and the intervention materials (patient information leaflet, assessment form, personalised health plan) were provided. All participants gave informed consent and ethical approval was granted, along with that for the other qualitative studies, by Bexley and Greenwich Research Ethics Committee (07/H0809/38).

Sixteen patients agreed to take part. Thirteen actually participated; five out of six came for the first group and eight out of 10 came for the second group. Reasons for not attending were not elicited. Those who participated (53% male) were aged between 48 and 86 years (mean 71 years). All but two, who were African Caribbean, described themselves as white British.

Discussions were tape-recorded and transcribed by RS. Transcripts were entered into NVivo 8 qualitative software. Coding was informed by the aims of the study. The coding frame and themes were discussed within the research team; we used notes of key discussion points (verified by participants) to guide our analysis.

Key findings of the discussion and modifications to the intervention

The participants were very focused on their need for someone to confide in and felt that a case manager would help with this.

The concept of self-management, in which the case manager would help them to solve their own problems, did not seem to be well understood. We planned to examine this in our exploratory study.

Participants agreed that PNs were the correct people to act as case managers because of their understanding of heart disease and its associated problems. Nurses should also be able to provide the continuity of care that participants emphasised as important.

Some participants disliked the planned use of goal-setting. Rather, participants were focused on wanting case managers to be a source of social contact. Based on our work with PNs, who complained of lack of time to manage these patients, this did not seem feasible. Instead, we felt that goal-setting and action-planning could be used to help patients obtain social contact. Furthermore, our literature searches identified good evidence for the feasibility of goal-setting in primary care.¹⁰⁶ This highlighted to us the importance, when designing interventions, of utilising multiple sources of evidence. We planned to explore the acceptability of goal-setting further in our exploratory study.

Finally, a minor point was that some of the wording used on the assessment form was not clear. We had developed our care plan format from the framework proposed by the Department of Health as the standard assessment for adults;^{107,108} this grouped health-related domains such as 'activities of daily living and mobility' under headings such as 'improved personal dignity and autonomy'. These higher-level headings appeared to confuse patients, so they were removed from intervention documents.

Discussion

Informed by the MRC framework for the design of complex interventions,³⁰ we conducted empirical studies and iterative literature searching to identify evidence and theory to develop and model a new PN-led PC intervention to improve mood and cardiac outcomes in sCHD patients with depressive symptoms.

Our approach is only one possible approach to developing a complex intervention using the MRC framework.³⁰ For instance, others¹⁰⁹ have drafted an intervention around a specific psychological theory and have tested theory-related hypotheses. However, we feel that a strength of our approach is that the intervention development was driven by the patients who will receive it and by the clinicians who will deliver it, with theory (i.e. self-efficacy theory and behaviour change theory) and evidence used to support choices concerning its content. The fact that all the studies reported here were funded by a single programme grant facilitated access to patients and allowed subsequent work to build on earlier findings in a timely fashion.

Furthermore, our approach led us to change our initial plans, which, as we have explained in *Chapter 1*, were to develop a nurse-led stepped care intervention. Our intervention development work clearly demonstrated a need for an intervention that could be tailored to the differing needs of individual patients; this could be included within a stepped care approach. It was also clear from this work that some PNs will need support to deliver an intervention for depression and that, since their workload is already very high, they would need convincing that any new intervention is feasible for them to deliver as well as effective for patients. Hence, with so much uncertainty around the feasibility of PN-led interventions for depression, we changed our plan to conduct a definitive RCT and decided to conduct an exploratory study which would provide this evidence and inform the best methods of a future definitive RCT.

The exploratory randomised controlled trial

In our exploratory study, two nurse researchers, independent of the participating practices, acted as case managers; one was a general and mental health nurse with experience of working in primary care, and the other was a general nurse who had subsequently qualified as a health psychologist. We also knew, from our cohort study, that CHD patients have high levels of comorbidity and that for some any cardiac event would have been several years ago; we therefore recruited only those patients with sCHD (i.e. reporting current chest pain) in order to ensure that they would understand the intervention in terms of their CHD. The study explored the acceptability, feasibility and potential costs of PN-led PC for primary care CHD patients who have depressive symptoms and current chest pain with the overarching aim to test the methods for a definitive trial. The full details of this study have been published in a peer reviewed paper by Barley *et al.*¹¹⁰ Here we summarise our methods and findings and report additional exploratory analyses.

Aims and objectives

1. To examine the rate of participant recruitment and reasons for non-participation.
2. To examine research procedures such as consent, randomisation/blinding and data collection.
3. To explore possible differences between primary outcome measurements and explore the most appropriate secondary outcome measures in relation to patients' reported problems.
4. To identify any trends between the groups in changes in self-efficacy and the impact of this on depression outcomes.
5. To determine the acceptability and feasibility of the intervention to practices and participants.
6. To explore whether or not the intervention can be standardised and whether or not therapist effects are likely to be important.
7. To explore potential costs of the intervention.

Methods

Design

The design was a patient-randomised pilot study with a control condition. We compared PN-led PC plus TAU for 6 months with TAU alone. The protocol for the study has been published;¹¹¹ deviations from the protocol are explained in the published report of this study.¹¹⁰ The study was reviewed and approved by the south-east London Research Ethics Committee (reference 10/H0808/5) and is registered with Current Controlled Trials International Standard Randomised Controlled Trial Number 21615909. The UPBEAT-UK Programme Grant Steering Committee, who decided that a data monitoring committee would not be necessary, oversaw the study.

Study setting

Practices in south London were recruited via the Greater London Primary Care Research Network (PCRN-GL). To be included, the practice had to keep a register of patients with CHD for the QOF¹¹² and be willing to liaise over patients in the PC arm when necessary.

Participant eligibility and recruitment

Inclusion criteria were sCHD (registered on GP CHD QOF register and reporting chest pain), reporting depression symptoms. All patients on practice case registers for CHD were asked by their GP for consent to contact from a researcher. Those consenting were contacted by a researcher and assessed for depressive symptoms using the PHQ-2⁸⁰ and for symptoms of current chest pain using the modified Rose angina questionnaire.¹¹³ Patients scoring ≥ 3 on the PHQ-2, and who reported currently experiencing chest pain (using the modified Rose angina questionnaire) were assessed further using the HADS.¹¹⁴ If they scored ≥ 8 on the depression scale of HADS (HADS-D) they were eligible to participate. Those consenting to participate were then randomised to either the intervention (PN-led PC and general practice TAU) or control (general practice TAU). Patients who were temporary registrants or currently hospitalised, or who a GP from the practice deemed actively suicidal, suffering from psychotic depression or non-English speaking were excluded.

As estimation of an effect size was not the focus of this pilot study, we used only a preliminary sample size calculation. An end-of-study mean difference between intervention and control score of ≥ 3 on the HADS-D, assuming a pooled SD around mean scores of 3.5, would require 30 participants per group for 90% power at the 5% significance level. To allow for loss to follow-up, estimated at 25%, our plan was to recruit 80 participants (40 per arm) into the study. The target figure of 3 was based on consensus discussion among clinicians at planning meetings and the assumed SD of 3.5 was obtained from the baseline cohort study. The estimate of attrition of 25% was considered reasonably conservative; it was felt that higher levels would have indicated lack of feasibility for implementing and testing the intervention. We estimated from the results of the UPBEAT-UK cohort study¹ that 10–15 practices each with around 10,000 patients would be needed to recruit 40 persons per arm.

Randomisation and blinding

Randomisation at patient level was conducted independently by the Mental Health and Neurosciences Clinical Trials Unit at King's College London. A random permuted block design was used to balance the numbers between groups. PC group participants were randomly allocated to one of two nurse researchers acting as case managers.

To ensure that those responsible for outcome data collection were blind to participants' allocation status, participants were asked at the beginning of each follow-up interview not to mention if they had been in contact with other study staff. The statistician was also kept uninformed of allocation status.

Outcome data collection

Research assistants who were blind to allocation collected data at baseline and at 1, 6 and 12 months post randomisation. Data were collected face to face at baseline and at follow-up via telephone.

The intervention: personalised care

This was delivered over 6 months, as detailed above.

Usual care

All patients received primary care TAU from their GP and/or PN; this may or may not include specific depression intervention such as antidepressant prescription or referral to talking therapy. The nature of TAU may vary between practices; we assumed that important differences in care delivery between the participating practices would be randomised between the groups.

Outcomes

Baseline demographic variables

All participants provided baseline demographic data including sex, age, ethnicity, socioeconomic status,¹¹⁵ employment and relationship status, living arrangement and lifestyle factors (e.g. smoking status, alcohol consumption, body mass index).

Aim 1: to examine participant recruitment

We made detailed records of recruitment rates. The number of participants at each stage of the study was documented and reasons for attrition were recorded.

Aim 2: to examine the study procedures

We recorded the number of randomisation errors [e.g. numbers of participants randomised despite being ineligible or who were randomised to the intervention (PC) but who did not receive it], and recorded rates and reasons for attrition and missing data for outcome measure at each time point.

Aim 3: to explore outcome measures

The preliminary primary outcome was the HADS-D. We observed depression status (response defined as $\geq 50\%$ decrease in score from baseline at follow-up and remission defined as a score of < 8 at follow-up) and severity (continuous score). We also explored the PHQ-9¹¹⁶ as an alternative measure of depression severity and extracted the number of GP/PN consultations for depression, antidepressant prescriptions and referrals to talking therapy during the 12-month study period from participants' medical records for both groups.

Our cohort study found that self-reported chest pain (measured using the modified Rose angina questionnaire) is associated with mood and social problems, so was also explored as a potential primary outcome for a future trial. The number of GP/PN consultations for heart-related problems during the 12-month study period was also extracted from participants' medical records as a proxy measure of participants' cardiac status in both groups.

Potential secondary outcomes explored were: anxiety [HADS – anxiety subscale (HADS-A)],¹¹⁴ well-being (Warwick–Edinburgh Mental Well-being Scale),¹¹⁷ quality of life [Short Form questionnaire-12 items (SF-12)],¹¹⁸ functional status (specific activity schedule),¹¹⁹ number of reported social problems¹²⁰ and adherence to antidepressant medication (if relevant – adapted version of Morisky Adherence Index¹²¹). To try to capture between-patient variety in reported problems and needs, we used a validated patient-generated measure of problems, function and well-being – the Psychological Outcome Profiles Questionnaire.¹²²

To reflect on how these outcome measures relate to the problems that patients consider important or feasible to change, we explored the types of needs and problems identified by intervention patients in collaboration with their case manager. This information was extracted from the notes made by nurse case managers during consultations. The Brief Illness Perceptions Questionnaire (BIPQ)¹²³ asks participants to 'Please list in rank-order the three most important factors that you believe caused your illness' – we also explored these responses.

Aim 4: to explore changes in self-efficacy

We used the General Self Efficacy Scale;¹²⁴ the scale has 12 items designed to assess perceived self-efficacy in order to predict coping with daily hassles and adaption after life events, with a high score indicating greater self-efficacy (range 10–40). We also used the BIPQ¹²³ to assess changes in perceptions about illness along the following dimensions: consequences, timeline (anticipated duration of illness), personal control, treatment control, identity (symptoms associated with the illness), illness concern, illness coherence (understanding of CHD) and emotional representations (emotional impact of CHD). Each of these eight items is scored 1–10. We examined General Self Efficacy Scale and BIPQ total scores as mediating factors for depression symptom reduction, remission and response.

Aim 5: to determine the acceptability and feasibility of the intervention

We recorded the time taken for assessment and the number and duration of follow-up telephone calls per patient, and explored participant satisfaction using an 11-item questionnaire devised for the study that was posted to the intervention patients after their 12-month follow-up.

Aim 6: to explore whether or not the intervention can be standardised and whether or not therapist effects are likely to be important

We developed a manual for the intervention, examined differences in patient outcomes between the two nurse researchers delivering the intervention and recorded nurse actions during the intervention.

Aim 7: to explore potential costs of the intervention

We calculated quality-adjusted life-year (QALY) gain using the European Quality of Life-5 Dimensions (EQ-5D).¹²⁵ The EQ-5D consists of five domains (mobility, self-care, usual activities, pain/discomfort and anxiety/depression) and each is rated 1 (no problem), 2 (moderate problems) or 3 (major problems). UK values were applied to the distinct health states derived from the EQ-5D to estimate the utility value for each patient at each time point and area-under-the-curve methods were used to calculate the QALYs.¹²⁶

Economic costs were calculated from a societal perspective. PC costs included the time spent by PNs with patients in face-to-face assessments and subsequent telephone reviews. A unit cost of £36 per hour was attached to the average intervention duration for each patient. Other service use was recorded using the Client Service Receipt Inventory¹²⁷ for the 6-month period preceding baseline, 6- and 12-month follow-ups. Health services included hospital inpatient and outpatient visits, GPs, psychiatrists, psychologists, physiotherapists, counsellors, nurses and other therapists. Unit costs were applied to service-use data using the NHS reference costs in 2009–10 prices¹²⁸ and the 2010 Unit Costs of Health and Social Care.¹²⁹ In addition, data were collected on the weekly number of hours of help (i.e. personal or child care, help in/ around and outside the house) received from friends and relatives of the patient. The unit cost of a home care worker was used as a proxy for costing informal care.

Medication use was recorded and costs were calculated based on the 2010 prices from the *British National Formulary*¹³⁰ and the Prescription Cost Analysis.¹³¹ The basic types of medication included psychological, cardiovascular (most common type), gastrointestinal, respiratory, eye, ear, nose and oropharynx drugs. Indirect costs of productivity loss because of CHD and comorbid depression were calculated using the human capital approach. For employed patients, productivity loss was the product of the days missed from work caused by sickness and the national mean daily wage in the UK,¹³² adjusted for full- or part-time working. However, only resource-use costs were considered in the cost-effectiveness analysis, as data on medication and sickness absence were self-reported and available for the baseline only (regarding the past 6 months).

Analysis

We conducted exploratory analyses using Stata version 11.2 (StataCorp LP, College Station, TX, USA). The intention-to-treat principle was used for all analyses. Owing to the exploratory nature of the analysis, *p*-values are reported for the preliminary primary outcome (HADS-D) only. We were fortunate to have a National Institute for Health Research-funded statistical fellow attached to our programme and were therefore able to conduct detailed exploratory analyses; these are explained fully in the published report of this study.¹¹⁰ Essentially, we developed a single statistical model to estimate the difference in mean scores between participants randomised to PC and TAU across the three follow-up points (1, 6 and 12 months). Other exploratory analyses compared the median number of responders ($\geq 50\%$ decrease in score from baseline at follow-up) and remitters (score of < 8 at follow-up) according to the HADS-D score between groups and explored changes in self-efficacy, the effect of nurse contact time and therapist effects using *t*-tests and chi-squared tests.

A health economics analysis used multiple regression, incremental cost-effectiveness ratios and the net benefit approach to estimate mean differences in costs and QALYs. Non-parametric bootstrap analyses were conducted to account for the highly skewed distribution of the cost data; results were plotted on a cost-effectiveness plane and used to estimate cost-effectiveness acceptability curves.

Results

Aim 1: examining recruitment

Seventeen practices were approached by the PCRN-GL and agreed to participate. Practices were recruited between October 2010 and June 2011; practice recruitment was therefore completed in considerably less than the 12 months planned in the study proposal, indicating that recruitment of practices for a definitive trial would be feasible.

We have published patient recruitment details in a paper by Tylee *et al.*¹¹¹ We summarise it briefly here. Of the 3325 people on the 17 GP CHD registers, 1001 consented to be contacted by returning a letter to their GP. A brief screen by telephone found that 126 were eligible for assessment (PHQ-9 score of ≥ 3 and reporting current chest pain on the modified Rose angina questionnaire). Of the 126 who were eligible, 40 had a HADS score of < 8 , two had experienced hallucinations, two had no current chest pain and one did not have sufficient English, therefore, 81 were found to be eligible. These were consented and randomised

(41 to intervention, 40 to control). The screening process involved minimal effort (return of a letter and a brief telephone screen). Target recruitment was achieved within 8 months, which was considerably faster than expected (we had planned a 12-month recruitment period based on experience of other studies); recruitment of patients for a definitive RCT, therefore, seems promising.

Baseline demographic and lifestyle data are reported elsewhere.¹¹⁰ There were 27 (66%) males in the PC group and 25 (63%) in the TAU group; mean age was 64.2 years (SD 13.0 years) in the PC group and 64.9 years (SD 8.5 years) in the TAU group. Any differences between the groups on the recorded demographic, lifestyle and outcome variables appeared small and the randomisation process appears to have produced balanced groups.

Past depression

Forty-eight participants reported having ever been diagnosed with depression (21/41 = 51% PC; 27/40 = 67% TAU). Of these, 12 had had one episode, seven had had two episodes, four had had three episodes and 23 reported having had four or more episodes (data on number of episodes were missing for two participants). Forty-six participants had previously received treatment for depression; of these, 41 had taken antidepressants and 29 had had talking therapy. Eighteen reported having received other treatment such as 'anger management', seeing a psychiatrist, electroconvulsive therapy, inpatient psychiatric care and relaxation and assertiveness courses. Our participants therefore represent a chronic and severe group.

Current depression

Twenty-four participants reported that they were currently receiving treatment for depression (9 in PC, 22%; 15 in TAU, 38%). According to the medical notes data, 13 in PC (32%) and 17 in TAU (43%) were taking some form of antidepressant medication at baseline. Despite being prescribed antidepressants, these participants were still reporting depressive symptoms. Nineteen participants reported their current episode had lasted > 12 months, two said it had lasted between 6 and 12 months, and three said it had lasted < 6 months.

Mean HADS-D scores [PC 11.6 (SD 3.3); TAU 11.4 (SD 3.0)] indicated moderate depression and mean PHQ-9 scores [PC 16.0 (SD 5.3); TAU 15.4 (SD 5.5)] indicated moderately severe depression in both groups. At baseline, according to the HADS-D, 21 (51.2%) participants in the PC group could be considered mild, 14 (34.2%) moderate and six (14.6%) severe. In the TAU group there were 19 (47.5%) mild, 15 (37.5%) moderate and six (15.0%) severe. For the PHQ-9, three (7.3%) were mild, 10 (24.4%) were moderate, 14 (34.2%) were moderately severe and 12 (29.3%) were severe in the PC group. In the TAU group, there were eight (20.0%) mild, eight (20.0%) moderate, 14 (35.0%) moderately severe and nine (22.5%) severe. The correlation between baseline HADS-D and PHQ-9 was $r = 0.48$ ($p < 0.0001$).

Coronary heart disease status

Patients were recruited if they reported current chest pain. Overall, 19 were current smokers and 53 were overweight or obese (see *Table 8*). Participants were also asked if they had high blood pressure and cholesterol, and diabetes; 56 out of 76 who responded (74%) said yes to high blood pressure (29/37 in PC; 27/39 in TAU), 42 out of 72 who responded (58%) said yes to high cholesterol (21/34 in PC; 21/38 in TAU) and 22 out of 80 who responded (28%) said yes to diabetes (12/40 in PC; 10/40 in TAU).

Aim 2: examining study procedures

Randomisation

Three patients who were ineligible owing to no current chest pain were randomised in error (two in the intervention arm); reasons for this are unclear. Based on the intention-to-treat principle these were included in all analyses, however, we conducted a sensitivity analysis and found that there were no differences in our conclusions when these patients were omitted from the analyses.

Blinding

Over the course of the study, there were many staff changes, especially among the research assistants responsible for outcome data collection. It was therefore not possible to test formally whether or not those collecting data remained blinded to the patients' allocation status. However, it was noted that some participants had reported contact with the case manager. Following the conduct of the main analyses, the statistician reported becoming unblinded; this was as a result of hearing that an additional participant had been randomised to PC.

Attrition

The Consolidated Standards of Reporting Trials diagram for the study is shown in *Figure 6* and has been published.¹¹⁰ By 12 months, six people in the intervention group had dropped out (two because they found participation upsetting, two because they felt too physically unwell to continue and two gave no reason) and one from the control group had dropped out (because they found participation upsetting). Two intervention group participants received baseline assessment but no intervention, as the nurses were unable to contact them. Overall, attrition was low ($7/81 = 9\%$), with data collected at one or more follow-up points for 79 people (98%).

Across the study period, completion was better for the TAU group than the PC group (*Table 6*). Completion was better among non-drinkers and those that drank the most (> 11 units per week), as well as those who were retired compared with being in paid employment across time points. Characteristics of completers are described in *Table 7*, which lists the demographics of those who completed follow-up and those who did not. HADS-D scores (*Table 8*) were marginally lower at 1 and 6 months among non-completers; however, they evened out by 12 months. We compared the models from our analyses with an additional model that controlled for any variables that were associated with missing follow-ups; these analyses did not give us any reason to alter any of our conclusions.

Data collection

The maximum number of observations available was 81 at baseline, 77 at 1 month, 74 at 6 months and 69 at 12 months. *Table 9* shows the number of (and percentage of available) missing scores for each questionnaire at each assessment point. Note: missing data for the Social Problems Questionnaire (SPQ) are not recorded because of confusion concerning whether items were missing or left out because they were not applicable (for analysis purposes no response was considered to mean 'not applicable' and therefore no problem in this area). Two of our outcome measures had no missing scores at any point: the modified Rose angina questionnaire and the specific activity schedule. The second question of the BIPQ (BIPQ2) had the most missing scores, with 14% missing at 6 months. For the other measures, between 5% and 10% of scores were missing at one or more assessment points for the General Self Efficacy Scale, the BIPQ (questions 3 and 4) and the Warwick–Edinburgh Mental Well-Being Scale; and $< 5\%$ of scores were missing for HADS-D, PHQ-9, BIPQ (questions 1, 5, 6, 7, 8), HADS-A and the SF-12 (mental and physical components). Therefore, our selected outcome measures appeared to be acceptable to the participants and would be feasible to use in definitive trial within a similar population.

WEMWBS, Warwick–Edinburgh Mental Well-Being Scale.

^a Percentage of the number of participants available at baseline = 81, 1 month = 77, 6 months = 74, 12 months = 69. Missing refers to questionnaire score missing owing to insufficient items completed to allow a score to be calculated or owing to participants not completing a particular questionnaire.

Depression

Depression outcomes are shown in *Table 10*. Both groups showed some improvement in depression symptoms (HADS-D score) at all time points, with the mean score in both groups moving from indicating moderate depression severity at baseline to mild severity at 12 months. We saw a similar pattern using the PHQ-9, with mean scores in both groups indicating moderately severe depression at baseline reducing to moderate depression at 12 months.

TABLE 10 Depression outcomes

Outcomes	PC	TAU	Mixed-effects model
HADS-D severity, mean (SD)			
Baseline	11.6 (3.3)	11.4 (3)	Mean difference −0.73 (95% CI −2.08 to 0.62; <i>p</i> = 0.29) ^a
1 month	11.0 (3.4)	10.0 (4.5)	
6 months	10.3 (3.8)	9.2 (4.6)	
12 months	9.5 (4.6)	8.8 (4.8)	
HADS-D remission,^b % (number of patients/total number)			
Baseline	N/A	N/A	OR 2.67 (95% CI 0.71 to 10.4; <i>p</i> = 0.15) ^c
1 month	14 (5/37)	30 (12/40)	
6 months	24 (8/34)	36 (14/39)	
12 months	34 (11/32)	41 (15/37)	
HADS-D response,^d % (number of patients/total number)			
Baseline	N/A	N/A	OR 1.33 (95% CI 0.38 to 4.61; <i>p</i> = 0.65) ^d
1 month	3 (1/37)	10 (4/40)

12 months	28 (9/323)	24 (9/37)	
PHQ-9 severity (PHQ-9 scores)			
Baseline	16.0 (5.3)	15.4 (5.5)	Mean difference −0.63 (95% CI −2.60 to 1.35; <i>p</i> = 0.54) ^b
1 month	14.8 (6.4)	13.0 (6.8)	
6 months	13.4 (7.0)	11.7 (6.5)	
12 months	12.6 (7.1)	12.0 (6.9)	

CI, confidence interval; N/A, not applicable; OR, odds ratio.

^a PC-TAU, based on 1 month, 6 month and 12 month combined; adjusted for time and baseline measure of outcome.

^b HADS-D score of < 8, odds of remission in the TAU compared with the PC group.

^c PC-TAU, based on 1 month, 6 month and 12 month combined; adjusted for time.

^d Decrease $\geq 50\%$ in HADS-D score from baseline and odds of response in the TAU compared with the PC group.

According to the HADS-D, there was a greater percentage of remitters in the TAU group compared with the PC group at 6 and 12 months; there was also a greater percentage of responders at 6 months in the TAU compared with the PC group, but by 12 months more PC group participants had responded. However, the mixed-effects models showed no significant differences between groups over time for any measure of depression and CIs were wide so an effect in favour of either group cannot be ruled out.

From the medical notes, across the 12-month study period, in the PC group, 31 participants (76%) saw their GP or PN regarding their mental health (total of 101 consultations recorded); in the TAU group, 29 participants (73%) made a mental health consultation (total of 102 mental health consultations recorded). Of those participants who were not treated for depression at baseline (i.e. no record of antidepressant prescription or talking therapy referral), three PC participants had received a prescription for an antidepressant [Citalopram (Cipramil®, Lundbeck), $n = 2$; Mirtazepine (Mirtazepine®, Merck Sharp & Dohme, Corp.), $n = 1$; one of these participants was also referred for 'counselling'] and one additional PC group participant had been referred to a 'psychiatric clinic' by 12 months; no participants in the TAU group had a new referral for depression treatment or a new prescription for an antidepressant at the end of the study.

Chest pain

The most notable difference between the PC and TAU groups was in self-reported chest pain (modified Rose angina questionnaire). At 6 months the proportion of patients who no longer reported chest pain was 37% in the PC group versus 18% in the TAU group and at 12 months it was 31% in the PC group versus 19% in the TAU group. From the medical notes across the 12-month study period, in the PC group, 34 participants (83%) saw their GP or PN regarding their CHD (total of 158 consultations recorded); in the TAU group, 29 participants (73%) made a CHD consultation (total of 170 consultations recorded). It is not clear from the notes whether these were routine or emergency visits, so we examined recorded accident and emergency (A&E) visits.

In the PC group, 10 participants (six for heart problems, two for other state reasons, two no reason recorded) visited A&E (total 13 visits: nine heart problems, two other stated reasons, two no reason recorded). In the TAU group, 15 participants (four for heart problems, five for other state reasons, six no reason recorded) visited A&E (total 26 visits: seven heart problems, six other stated reasons, 13 no reason recorded). PC participants therefore made fewer A&E visits (24% in PC vs. 38% in TAU), although missing data concerning the reason for these visits makes this information difficult to interpret.

Preliminary secondary outcomes

At 6 and 12 months both groups improved on all outcomes (*Table 11*); these data have been published.¹¹¹ There was no evidence for an interaction between time point and study arm for any outcome, so a differential effect over time appears unlikely.

TABLE 11 Mean scores (SD) for outcomes other than depression at 1, 6 and 12 months

Aim 3: validity of outcome measures in comparison with participant-reported problems

Using the BIPQ, participants were asked to list the three most important problems that caused their illness (CHD). Sixty-one participants gave at least one reason (these data are published online as an appendix¹¹⁰). The most common reason given was 'genetics or heredity', followed by lifestyle factors such as smoking, poor diet and lack of exercise. Mood problems, especially stress and work-related stress were also mentioned, and comorbid or past health problems were also blamed. Four patients mentioned relationship problems and one mentioned financial problems.

Participants in the PC group ($n = 41$) identified 21 types of problem as contributing to their depression and which were addressed during the intervention (up to three problems per patient); most common were pain (chest and other pain, e.g. arthritis) ($n = 18$), lack of exercise ($n = 17$), difficulty sleeping ($n = 13$), anxiety ($n = 11$) and being overweight ($n = 11$). Reported problems and whether or not they were addressed during the intervention are published online as an appendix.¹¹⁰

Participants therefore explained both their CHD and their depression in terms of wide-ranging problems that appeared similar for the two conditions; lifestyle problems in particular were associated with both.

Within our study, mood outcomes were assessed using the HADS (depression and anxiety) and the PHQ-9 (depression); however, we had no measure of change in lifestyle-related outcomes. The PC intervention was aimed at tackling the problems that each participant felt were important rather than addressing specific cardiac risk factors; however, in view of our current finding that patients do consider lifestyle factors known to be associated with CHD as contributing to their depression, inclusion of a measure of change in cardiac risk factors should be considered for a definitive trial of PC. It will be important to select a measure that captures the variation between participants in terms of which risk factors they want to address; a validated measure of goal attainment may therefore be appropriate.

Aim 4: exploring changes in self-efficacy

Self-efficacy improved over the course of the study (see *Table 11*). At 12 months, the PC group had a mean increase of 2.5 points versus 0.9 points in the TAU group, suggesting a greater increase in self-efficacy in the PC group; however, the mixed-effects model indicated no difference between groups over time (adjusting for baseline self-efficacy): mean difference -0.58 (95% CI -3.05 to 1.89).

At 6 and 12 months the overall illness perceptions score and most measured dimensions showed improvement in both groups, though differences between groups were small (*Table 12*). The mean improvement in overall score from baseline to 12 months was greater in the PC group than in the TAU group: 7.8 points versus 2.5 points. As expected, the biggest difference in mean improvement between the PC and TAU groups in dimension scores was in personal control (mean change in BIPQ from baseline = 1.5 for PC group vs. 1.1 for TAU at 6 months; and 1.1 for PC vs. 0.1 for TAU at 12 months); however, the mixed-effects model suggested no difference between groups over time (adjusting for baseline total BIPQ score): mean difference -0.42 (95% CI -4.57 to 3.72).

Controlling for changes in self-efficacy or overall illness perceptions had little effect on change in depression over time, whether or not considering depression severity, remission or response (*Table 13*). Since CIs were wide, change in favour of either PC or TAU cannot be ruled out.

TABLE 13 Effect of controlling for changes in self-efficacy and illness perceptions on depression outcomes over the study period

Depression	Mixed-effects models ^a (95% CI; <i>p</i> -value)		
	Time point	Self-efficacy ^b	Illness beliefs ^c
Severity (mean difference)	–0.73 (–2.08 to 0.62; 0.29)	–0.88 (–2.11 to 0.36; 0.16)	–0.57 (–1.90 to 0.77; 0.40)
Remission (odds ratio)	2.67 (0.71 to 10.05; 0.15)	3.15 (0.64 to 15.50; 0.16)	3.26 (0.94 to 11.24; 0.07)
Response (odds ratio)	1.33 (0.38 to 4.61; 0.65)	1.02 (0.26 to 3.95; 0.98)	1.27 (0.34 to 4.66; 0.72)

a Examining difference in HADS-D score and depression remission and response in TAU vs. PC groups controlling for HADS-D baseline score, treatment arm and time.

b Is also controlling for change in General Self Efficacy Scale score across the study period.

c Is also controlling for change in total BIPQ score across the study period.

Post-hoc analyses

As anxiety symptoms were high at baseline, we also explored HADS-A score as mediator for improvement in depression. Controlling for anxiety slightly reduced the difference in depression symptoms between the groups over time: mean difference –0.43 (95% CI –1.48 to 0.63; *p* = 0.43). Controlling for anxiety considerably reduced the odds of remission in the TAU group versus PC group in favour of the PC group: odds ratio (OR) remission in TAU versus PC group 0.42, 95% CI 0.10 to 1.68; *p* = 0.22, which suggests that changes in anxiety symptoms may be a mediator for depression remission. The odds of depression response in the TAU group compared with the PC group were also slightly reduced when anxiety scores were controlled, although the odds were still in favour of TAU (OR 1.12, 95% CI 0.32 to 3.94; *p* = 0.86). None of these analyses showed a statistically significant effect; all changes in effect were small and CIs were wide so we cannot rule out benefit for PC or TAU.

Aim 5: exploring acceptability and feasibility of personalised care

Nurse time used for intervention

Intervention patients (*n* = 41) received a mean of 203 minutes (SD 100 minutes) of nurse time [78 minutes (SD 19 minutes) for assessment, 125 minutes (SD 91 minutes) in telephone follow-up calls over 6 months].

The mean number of follow-up calls was nine (SD five); the mean duration of calls was 14 minutes (SD 4 minutes). The nurses arranged a time to call the patient, but sometimes patients did not respond; there was considerable variation between patients in the number of failed follow-up contact attempts by nurses over the 6-month intervention period (range 0–32), but on average nurses made 2.8 calls for every successful contact.

Effect of intervention intensity

The amount of time spent talking to the nurse varied considerably between patients (range 74–406 minutes), so we used the median duration (167 minutes) to divide the participants into high ($n = 20$) and low ($n = 19$) 'dose' groups. There were no significant differences ($p > 0.05$) between the groups at baseline in depression [HADS-D mean: low-dose group 11.0 (SD 3); high-dose group 12 (SD 3.7)]. The magnitude of improvement in depression over time was greater for the high- compared with the low-dose group and fewer high-dose patients had chest pain at 6 and 12 months, although the mixed-effects models indicated little difference between the groups: depression mean difference -0.72 , 95% CI -3.03 to 1.60 ; chest pain OR 0.34 , 95% CI 0.01 to 7.53 .

Patient satisfaction with personalised care

Of the 41 PC participants, 21 completed and returned the satisfaction questionnaire. The questionnaire and responses are shown in *Table 14*. On the whole, patients reported finding the different elements of

TABLE 14 Patient satisfaction with the PC intervention

	Number of responses

	Yes			No		
Would you like your GP practice to provide a service such as this?	15			0		

N/A, not applicable.

a The name of the nurse with whom the patient had been working was inserted.

the intervention (assessment, care plan and follow-up calls) helpful. They also found that the intervention helped them communicate with other health professionals such as their GP. Most respondents agreed or strongly agreed that the nurse was able to answer their questions about their mood, heart or other health problems and that they could understand the information given, and that the nurse provided support and encouragement and had a courteous manner. Of the 15 patients who responded to this question, all said that they would like their GP to offer a similar service.

The patients were also asked which aspect of working with their nurse they had liked best and least. Seventeen patients responded regarding what they liked best: two patients liked 'everything' or 'all'; several comments referred to the patient's pleasure in having someone pleasant to talk to:

it's just good to talk to somebody.

sympathetic helpful and friendly approach.

[Nurse] is a nice person and very pleasant.

Other comments were more specific and referred to the nurse's ability to treat them as an individual when offering advice and understanding:

Their personal interest in me as a patient and not just a number, like you feel in hospital sometimes. Their interest in my problems and how they could help me with my problems and difficulties and trying to help, in getting me to understand my problems and difficulties and that there was a light at the end of the tunnel and they has been so good to me in that area and I'm hoping I can do their help worthy.

They always had a nice manner (sic). Listens very well and after what I've been through they had a good answer and good advice. Please thank [nurse] for their time.

their advice about routine – listening to radio and when you believe somebody care about you – here I am alone, no family (except my children), no friend. We need such as this service.

Regarding what they liked least: 10 patients responded 'none' or 'N/A' [not applicable]; one patient responded 'forms'; another, who had been positive about the intervention, appeared to indicate that they had found participation difficult:

Knowing the value of time it was so difficult to convince myself that I was not wasting both (the Nurse's) and my time operating this plan. I fought hard against this feeling.

This patient's comment in the 'liked best' section seemed to suggest that they nevertheless valued the intervention, so their earlier comment may be reflective of their depressed state:

Honestly I didn't really like any of it. I feared that I was too set in my regimes to open my soul and shortcomings. However I understood that it was important for me to proceed and tried to give it my full attention. But it wasn't likeable.

Aim 6: exploring standardisation and therapist effects

Intervention fidelity

As planned, the nurse case managers used a range of nursing and behaviour change techniques to help patients address their problems. Classifiable behaviour change techniques reported by nurses were: general encouragement, information linking health and behaviour, goal-setting and action-planning, barrier identification and focus on past success. Other nurse-reported actions included lifestyle advice,

signposting (e.g. to relevant local resources such as leisure or day centres), promoting adherence to therapy and supportive counselling.

There was also some evidence of collaborative care. The nurse case manager contacted the patient's GP (10 patients), the patient's PN (four patients), social services (one patient) or another professional, for example IAPT worker or other therapist, occupational therapist, community mental health nurse, physiotherapist, housing or benefits officer (17 patients). With the patient's permission, the nurse case managers consulted a family member of four patients.

Therapist effects

The patients of Nurse 1 had a higher mean baseline HADS-D score (12.4 vs. 10.9, Wilcoxon rank-sum test; $p = 0.07$). However, the random-effects model (combining data from 1, 6 and 12 months) indicated little difference in the average therapist effect on the HADS-D score across the time points (adjusting for baseline HADS depression score): mean difference -0.86 (95% CI -2.81 to 1.10).

Regarding self-reported chest pain, of Nurse 1's (registered general nurse and health psychologist) patients, 44% continued to report chest pain at 6 months, compared with 79% of Nurse 2's (registered general and mental health nurse) patients ($p = 0.03$). In the random-effects model, the odds of reporting chest pain across the study period were higher for Nurse 2 than for Nurse 1 (OR 7.80, 95% CI 0.88 to 69.40).

Aim 7: examine the potential cost of personalised care

The average EQ-5D utility scores at baseline were slightly higher for the PC group (see *Figure 7*, which is also published elsewhere¹¹⁰), although the difference between groups was not statistically significant (95% CI -0.98 to 0.25 ; $p = 0.40$). By the 1-month follow-up, the TAU group had a higher utility score, and this difference was maintained up to the 12-month follow-up [95% CI -0.26 to 0.11 ; $p = 0.422$ (at 6-month follow-up: 95% CI -0.27 to 0.11 , $p = 0.408$)]. In terms of QALYs, the TAU group showed an incremental QALY gain of 0.038 compared with PC over the 12-month treatment period. In *Figure 7* the area between the two curves represents the QALY gain for the control group.

Service use and costs

Service use was fairly similar between the intervention and the control groups during the study period (*Table 15*, which is also published online as an appendix to our paper¹¹⁰). Hospital services were used more intensively by the TAU group than the PC group at all time points, with inpatient and outpatient care

being the most frequently used services. The TAU group incurred higher inpatient costs than the PC group at each time point (particularly at baseline and at the 12-month follow-up). Few patients used day hospital services, but the costs incurred were high for both groups. The majority of patients received care from GPs and the costs of this were similar between the groups. Informal care was used slightly more among patients in the PC group than in the TAU group. Average total costs at each time point were lower for the PC group than for the TAU group. However, the differences were not statistically significant. For the PC group, the intervention itself accounted for only 6.7% of total costs.

Cost-utility analysis

Of the total 81 participants, cost and QALY data at each time point were available for 68 patients (84%). Cost-utility results yielded an incremental cost-effectiveness ratio of £29,921 per additional QALY. Cost-effectiveness plane and cost-effectiveness acceptability curves were produced from bootstrapped resamples. The distribution of the cost-effectiveness point estimates on the cost-effectiveness plane (Figure 8, which can also be found in Barley *et al.*¹¹⁰) indicated a strong likelihood of cost savings for the PC group compared with the TAU group. The point estimate of the incremental cost-effectiveness ratio falls in the south-western quadrant, representing the situation where the PC group has reduced costs and worse outcomes. The second most likely result is that PC results in lower costs and better outcomes (south-east quadrant).

The cost-effectiveness acceptability curves (Figure 9) for the PC group compared with the TAU group was downward sloping. There is a greater likelihood of PC being the most cost-effective option up to a QALY threshold of £3035.

Discussion

We developed a PN-led PC intervention, which was designed to be easily implemented within practice in order to improve current primary care. In this patient-randomised pilot trial we explored the acceptability, feasibility and potential costs of the intervention for primary care CHD patients who have probable concurrent depression and current chest pain. We also explored the feasibility of the trial protocol to inform the methods of a definitive trial.

Feasibility and acceptability of personalised care

The PC intervention appeared to be feasible and acceptable for use in current primary care: a short amount of nurse time was needed, engagement with the nurse case managers was high and most of the PC group participants who returned our questionnaire reported satisfaction with all aspects. To further understand participants' experience of the intervention, we have interviewed a subsample of 12 PC group participants. We used purposive sampling to select participants by age [$>/\leq 60$ years], sex, nurse case manager, depression (HADS-D $>/\leq 10$) and nurse case manager impression of depression response. Owing to research assistants leaving the programme for positions with longer-term prospects, these data are yet to be analysed.

As expected, this exploratory study confirmed the findings of our earlier qualitative work that patients with CHD and depression symptoms report a wide range of problems that they consider contribute to their low mood. The PC intervention enabled patients to identify and address these problems with the nurse case managers. This is an improvement on current care for these patients since management of depression and/or psychosocial problems is not routinely addressed in this population,^{31,59} despite recent routine depression screening under the QOF.¹¹² Compared with the widespread organisational change that would be needed for collaborative care interventions as trialled in the USA,¹² our PC intervention appears to offer an enhanced form of TAU which could be implemented easily in current primary care practice. Evidence from the UK-based proactive care by PNs for people with depression and anxiety (ProCEED) trial^{133,134} that care reviews delivered by PNs acting as case managers were acceptable to patients with long-term depression supports this.¹³⁴

We explored a wide range of outcomes focusing on depression, as measured by the HADS-D as a potential primary outcome. Findings tended to show slight benefit for TAU compared with PC for depression symptoms, remission and response, except that at 12 months more PC participants had responded. However, differences between groups were very small and wide CIs mean that improvement with either PC or TAU cannot be ruled out. Our mixed-effects model indicated that PC would be unlikely to do much harm compared with TAU (mean difference -0.73), but could improve symptoms up to 2.1 points on the HADS-D (95% CI -2.08 to 0.62). We see little reason to change to a different outcome.

Accepted health psychology models agree on two factors important for behaviour change: belief in the importance of an outcome and belief in capacity to succeed (self-efficacy). Our intervention facilitated participants to work on outcomes important to them, and we used techniques such as action-planning to increase self-efficacy. Our data indicated that self-efficacy and illness perceptions, especially personal control, which is closely related to self-efficacy, were increased in those receiving PC but the difference from the increase in TAU group participants was not great.

Although both groups improved on all our measured outcomes, there were no large differences between groups, except in self-reported chest pain, which was also an inclusion criterion for the study. Our cohort study indicated that chest pain has a range of negative impacts and is therefore an important outcome to study.

Potential costs of personalised care

There were no great differences in service use and costs between PC and TAU, with the exception of inpatient care, which also accounted for a substantial proportion of total costs. Overall, it appears that PC reduced costs compared with TAU, but produced slightly lower benefits in terms of QALYs. This may appear counterintuitive given the other findings, but the utility scores underlying the QALY calculations were fairly similar and did not change much over time. Costs may have been underestimated owing to reliance on patient self-report in service use, the lack of medication and sick-leave data at all time points and the approach used to quantify informal care. Informal care constitutes a major cost driver in chronically ill populations. In this analysis, the 'proxy good method'¹³⁵ and the unit cost of home care worker was used to calculate informal care. However, in a future trial, an alternative cost, such as the national minimum wage, could be used to quantify informal care in the context of a sensitivity analysis. A future trial should also test whether or not a longer time horizon is needed for this particular patient group to benefit from an intervention of this kind. It may be considered unusual to include a full economic analysis in a feasibility study and, therefore, these results should be seen as exploratory.

Implications of clinical findings for a future trial of personalised care

An implication of the lack of difference between PC and TAU and the small degree of change in depression symptoms detected is that, if depression symptoms are to be used as a primary outcome in a definitive trial, a large sample size would be required to replicate difference of the order found here [e.g. using the HADS-D mean and SD (PC: mean 10.3, SD 4.6; TAU: mean 9.2, SD 4.6) at 6 months an achieved sample size of 368 per group would be required for 90% power at a 5% significance level (two-sided)]. This would be increased considerably if a cluster design were employed, which would be necessary to reduce contamination if PC were tested using PNs based in practice, and would also need to be increased to take account of attrition. On the other hand, a clinically significant effect of 3 on HADS-D, as originally proposed, would require fewer. The main implications for planning are the somewhat higher SD than that originally assumed (4.6 compared with 3.5), and the lower attrition rate (13% compared with 25%). The recruitment of practices to achieve these figures is another factor to be considered in planning. The fact that only a small improvement in depression symptoms was found over the entire sample is consistent with systematic review evidence indicating that even intensive evidence-based psychological treatments, such as CBT, problem-solving and pharmacological intervention with selective serotonin reuptake inhibitors, have only a small effect on depression in people with CHD.^{96,136}

Furthermore, our sample appears to represent a hard-to-treat group: the level of depression symptoms was high, more than half reported recurrent depression and more than one-quarter reported that they were receiving depression treatment at baseline and yet still reported depression symptoms. In addition, a large longitudinal cohort study ($n = 1209$)¹³⁷ has found that pain, mediated by baseline severity of mood symptoms, was predictive of a worse course of depressive and anxiety disorders; all of our participants reported current chest pain, which was an inclusion criterion. A 3-point change in HADS-D score (which a trial of this size could have detected) after 6 months of relatively low-intensity intervention may therefore be an unrealistic expectation and a more intensive intervention for depression with engagement over a longer period may be needed for patients such as these. Our data, which suggest that receipt of more nurse time is associated with greater improvement in depression and self-reported chest pain, support this.

As well as chest pain, anxiety comorbid with depression is predictive of a worse depression outcome;¹³⁸ our participants reported high anxiety levels and we found some evidence of anxiety as a mediator for depression improvement. In a future trial, more active treatment of anxiety should be tested, particularly when associated with chest pain.

The potential to detect differences between PC and TAU in our trial may have been reduced because TAU is itself an active intervention: at baseline 43% of the TAU group versus 32% of the PC group were prescribed antidepressants (according to their medical notes), and we were unable to control for this difference in our analyses. It is also possible that TAU may have been intensified during the trial: during our qualitative work GPs and PNs reported greater awareness of the problem of comorbid depression and CHD as a result of participation in our cohort study, the same may apply to participation in our RCT. This may have led to more than usual intervention in the TAU group, although from the medical notes it appeared that the number of mental health consultations were similar for both groups. In a future trial, changes in TAU during the trial should be recorded systematically.

We hypothesised that the intervention would increase self-efficacy to achieve desired outcomes which would lead to improved depression outcomes. However, the small recorded changes in self-efficacy and related illness perceptions had little effect on depression outcomes. This may have been expected: a difference between our intervention and that of others that have not found improved self-efficacy¹³⁹ following self-management intervention is that our participants chose the outcomes on which to work on, that is, they identified the factors that they felt contributed to their low mood, rather than being required to work directly on their depression. A better examination of the theory behind our PC intervention would be to explore the effect of changes in self-efficacy on a measure of goal attainment, then test the effects of goal attainment on depression over the long term, although this would require a complex trial. Fewer PC compared with TAU participants visited A&E (24% vs. 38%), which may indicate increased self-efficacy in self-management in the PC group, though in a future trial a more robust measure than self-report of A&E attendance should be used to examine this, for instance Hospital Episode Statistics.¹⁴⁰

The possibility that our PC intervention may impact on reported chest pain requires further investigation. We are unable to determine whether or not self-reported chest pain in our trial participants was of cardiac origin. It is estimated that in half of all patients presenting with chest pain, the pain is of non-cardiac origin.¹⁴¹ A high-quality review of psychological interventions for chest pain in patients with normal coronary anatomy (15 studies, 803 participants),¹⁴² suggests a modest to moderate benefit, especially for CBT and possibly hypnotherapy. Our trial indicates that non-pharmacological intervention may also be effective for chest pain in patients with CHD. Given the impact of chest pain on patients' quality of life, mood and on the health service, self-reported chest pain may be an important primary outcome for a future trial. However, since determination of the causes of self-reported chest pain is complex, this should be supported by a more objective measure of cardiac status, such as heart rate variability, which is a predictor of a range of cardiac outcomes and associated with a number of psychological risk factors for CHD.¹⁴³

Lessons learnt concerning delivery of personalised care

The PC intervention was designed, informed by the findings from our qualitative work, to facilitate both patient choice and clinical judgement, so variation in intervention delivery was expected. However, we produced a manual for the intervention and the nurse case managers reported using its key elements of behaviour change interventions, signposting and liaison with other professionals. In weekly study group meetings, the multidisciplinary clinical team was satisfied that the PC was delivered as planned. Exploratory investigation of therapist effects indicated no difference in depression outcomes between the patients of the two nurse case managers, but that the patients of the nurse case manager with more health psychology experience may have had a greater reduction in self-reported chest pain. There was a very small sample size for this analysis, so this finding should be interpreted with caution, but it suggests that training in the behaviour change aspects of the intervention is important for case managers. However, other studies have shown that even nurses and GPs trained in behaviour change techniques may have

difficulty applying them.^{144,145} Further research into how best to train, or whether or not non-psychologists can be trained, to work more psychologically to increase the effectiveness of care is needed. A future trial of PC could test it as delivered by IAPT psychological well-being practitioners (PWPs).

An alternative approach would be to make greater effort to ensure that depressed patients managed using PC receive guideline-informed treatment. Multidisciplinary collaboration to ensure receipt of available, effective depression treatment has been a key element in a number of successful trials of complex interventions for depression in primary care patients.^{12,146,147} In this trial, four participants in the PC group, compared with none in the TAU group, received new depression treatment (antidepressant treatment or psychological treatment) by the end of the trial. The nurse case managers often contacted other professionals involved in the care of the majority of PC group participants. However, the nurses reported difficulty in accessing some of the participants' GPs and PNs (e.g. several telephone attempts needed, lack of response to e-mails); this limitation may be overcome by using case managers based within the GP surgery. However, even when contact was made, patients may not have received guideline-informed depression treatment (e.g. one GP was reluctant to prescribe antidepressants to a severely depressed patient despite advice from the nurse case manager because of expressed anxiety concerning multipharmacy and because IAPT services were unavailable in some areas). This suggests that in a future definitive trial, nurse case managers should be embedded within study practices to increase multidisciplinary collaboration (e.g. by planned times for discussion of cases with GPs and PNs, as is often the case in collaborative care) and means of ensuring that patients can access guideline-informed depression treatment should be predetermined.

Lessons learnt concerning the study protocol

Overall, the findings suggest that the trial protocol was feasible, with high levels of compliance and acceptability. For instance, attrition was < 10% and rates of missing data for most outcomes were low, despite the large number of measures. The PCRN-GL was responsible for practice recruitment, which was achieved well within our predicted time frame. This was helped by their prior knowledge of practices willing and able to conduct such research. Patient recruitment was also as expected and was in line with other studies of depression interventions in primary care.^{146,148,149} Only around one-third of patients invited to participate by his or her GP provided consent to contact; this was also the case in our cohort study. Use of this 'opt-in' system appears to result in substantial loss of potential participants; however, this is the usual method of recruitment for studies conducted in UK primary care. All of the patients meeting our inclusion criteria at baseline agreed to be randomised. Low attrition and high acceptability suggest that people with CHD, depressive symptoms and chest pain are receptive to additional support.

Conclusions

We have developed an intervention that is acceptable to primary care CHD patients who have probable concurrent depression and current chest pain, and which is feasible for use in current practice. The PC intervention could, we think, be delivered by PNs, although training in behaviour change techniques will be necessary. IAPT PWPs may also be potential case managers, but they would need training in long-term condition management.

Depression symptoms in CHD patients who report chest pain appear difficult to treat, as evidenced by this trial and by previous work.⁹⁶ Our data suggest that more nurse time was associated with improved outcomes, so more intensive follow-up should be included in future use of the PC intervention.

In this trial, collaborative working to ensure that patients received guideline-informed depression intervention was not optimal; this may be improved by using case managers based within trial practices and having agreed methods for providing access to guideline-informed care. Other trials^{12,146} suggest that this will improve depression outcomes.

It is uncertain which outcomes, other than depression, should be used in a future trial of PC. Our data suggest that self-reported chest pain may be important, but given the complexities in the relationship between self-reported chest pain and cardiac outcome, use of this measure should be supplemented with a more objective measure of cardiac health, for instance heart rate variability.

Our data also suggest that the underlying theory of our PC intervention, that increased self-efficacy to achieve desired outcomes would lead to improvements in depression, needs further testing. Since participants chose a wide range of problems on which to work on, it was difficult to determine how many achieved their goals; a measure of goal attainment should be included in a future trial. However, changes in self-efficacy were small and more intensive psychological intervention may be needed to achieve greater improvement. Longer follow-up is likely to be needed to see impact on depression outcomes.

The trial protocol appeared, on the whole, to be successful with high levels of compliance and acceptability. However, we found, in common with other studies, that large numbers of patients have to be approached and screened for a sufficient number of CHD patients with both chest pain and depressive symptoms to be randomised. This makes such trials costly.

In so much as patients were able to address the wide variety of problems that trouble them, the PC intervention represents enhanced care, which may also be cheaper than TAU. If a fair test of the differences between this low-intensity, quality improvement intervention and TAU is to be made, in future trials it will also be important to monitor more closely any changes in TAU over the course of the trial which may occur owing to increased awareness in participating clinicians of the need to manage depression in people with CHD.

Chapter 5 Cohort study (work package 3)

Objectives and methods

In this chapter we describe the relationship between depression and chest pain in primary care patients recruited into the study from the GP QOF CHD registers. The aims, objectives and methods have been presented in detail elsewhere¹ and will be summarised here.

Objectives

The objectives of the cohort study were to:

1. determine the prevalence, incidence rate and risk factors of depressive disorders in primary care patients with CHD
2. explore and describe the course and prognosis of physical and depressive symptoms among primary care patients with CHD over a 3-year period
3. determine the effect of depression on mortality, symptom severity and pain in primary care patients with CHD.

Service use, service costs and lost employment costs will be described separately.

Methods

The cohort study methods, instruments and analysis plan have been described elsewhere.¹ This was a naturalistic cohort study of primary care patients recruited from QOF CHD registers held by GP practices in south London. All participants on these registers were eligible for inclusion in the study as long as they were > 18 years of age and not temporarily registered with their GP. Eligible consenting patients were assessed at baseline and then followed up at 6-monthly intervals for a period of up to 4 years. We report on the 3-year follow-up data here. All patients were eligible for 36 months follow-up at the end of the study. A smaller population was eligible for a 4-year follow-up (and will be analysed in the future). The measures used at baseline and follow-up are shown in *Table 16*, previously published as table 1 in Tylee *et al.*¹ Not all measures have been used in the analyses presented here. For more details on the instruments used, see *Appendix 4*.

The reporting of chest pain by cohort members was recorded at each wave of follow-up. Chest pain is the cardinal symptom of CHD and the key to a clinical diagnosis of angina pectoris. We report here the prevalence rate of this physical symptom at baseline and the outcome in terms of cardiovascular events (e.g. MI) or continued exertional chest pain (i.e. patients reporting exertional pain on most occasions). We have analysed the relative roles of depression, anxiety and quality-of-life scores for these outcomes.

Chest pain assessment

We used the Rose questionnaire¹¹³ to assess the severity of the symptomatology (i.e. chest pain) of CHD. Devised in the 1960s for the purpose of detecting angina pectoris in field studies, it has been widely used since. The original validation criterion was agreement with CHD diagnosis in GP medical notes but since then it has been used as a useful predictor of subsequent cardiovascular events in the longer term.^{157–160} On the other hand, the agreement between a positive response on the Rose and concurrent clinical testing for evidence of CHD can be poor.^{161,162} It is used in both a long form in field studies and, as the short form of the Rose questionnaire has equivalent predictive power, the short form is often preferred. We describe how both the short form and the long form are rated below. Pain on exertion seems to be the key symptom to predict subsequent problems.¹⁶³

The short form is outlined in *Table 17* below and the additional questions for the long form are shown in *Table 18*.

To assess cardiac outcomes, all cardiology notes, investigations and interventions were collected from the GP notes by a medical doctor on the team (JP) and entered into an encrypted Microsoft Access® 2007 database (Microsoft Corporation, Redmond, WA, USA). The dates of each visit to a cardiologist, each investigation for a cardiac-related problem and each visit to a rapid access chest pain clinic, A&E or hospital admission for a cardiac investigation or intervention (e.g. bypass graft, angioplasty) were recorded. We also recorded any GP visit for cardiac-related problems or regular follow-ups. The data to be inputted and the specific definitions of cardiac investigations were decided before the hard copies were examined, with exception to the 'rapid access chest pain clinic' category. The GP notes were re-examined to gather this

TABLE 17 Rose items used for scoring the short version: specific wording and order of items given

Rose angina questionnaire item	Response required for scoring
1. Do you ever have any pain or discomfort in your chest? (Rose question 1)	Yes
2. When you walk at an ordinary pace on the level does this produce the pain?	No (grade 1)/yes (grade 2)
3. When you walk uphill or hurry does this produce the pain?	Yes
Scoring criteria for the short Rose angina questionnaire: grade 1 angina: chest pain + pain uphill; grade 2 angina: chest pain + pain uphill + pain on the level. (Experiencing chest pain when walking on the level is classed as more serious than pain only when walking uphill.)	

TABLE 18 Rose angina questionnaire items used for scoring the long version: specific wording and order of items given

Rose angina questionnaire item	Response required for scoring
4. When you get any pain or discomfort in your chest on walking, what do you do?	Stop or slow down
5. Does the pain or discomfort in your chest go away if you stand still?	Yes
6. How long does it take to go away?	≤ 10 minutes
7. Diagram

7.2 Diagram cross section	Middle centre chest pain
7.3 Diagram cross section	Upper left chest pain and middle left chest pain

extra information and all data were entered into the Access database before any analysis of cardiac investigation data occurred. Numerous records per individual were condensed into variables that denoted: (a) the first cardiac investigation to occur within two time points would be recorded per person; and (b) the most severe cardiac investigation to occur within two time points would be recorded per person.

Thus, a cardiac outcome variable with seven hierarchical categories was created using a combination of the short form of the Rose angina questionnaire, the GP medical notes and publicly available mortality records:

- no chest pain: score of 0 on the short Rose angina questionnaire
- chest pain: positive response to the Rose angina questionnaire item
- exertional chest pain: positive classification of grade 1 or grade 2 angina as defined by the short form Rose angina questionnaire
- rapid access: any visit to the rapid access chest pain clinic, or any visit to A&E or emergency hospital admittance where cardiac-related chest pain was the diagnosis
- bypass graft or angioplasty: intervention reported on GP medical notes or cardiologist/cardiology service notes
- MI: occurring at any point during the follow-up period
- death: any cardiovascular-related cause of death included (i.e. cardiovascular and cerebrovascular).

For the purpose of the longitudinal analysis, the most severe outcome was assigned to the time point at the end of the period where the outcome occurred. MIs and deaths had to be combined for some analyses, when there were insufficient numbers to fit full models. When linking cardiac investigation and mortality data with interview data at specific time points, deaths and cardiac investigations were coded into time points at the end of the 6-month window between interviews. If a participant had a recorded cardiac investigation within the 6 months before baseline, this was recorded in the baseline time point. All cardiac investigation data as described, with dates of the investigations, were merged into the cohort data set. The aim of this time assignment was to produce data where mental health status could be clearly identified in its temporal relation to cardiac outcomes (the actual date of death was, however, used for a more detailed and specific study of mortality).

Mortality data was gathered from a number of sources, including case notes and publicly available records. The deaths of the cohort participants were tracked in the first instance via the practice manager at the different GP surgeries, where we asked for date and cause of death. In those cases in which the participant had moved away from the surgery, we contacted the primary care support services within the specific boroughs. Further to this, we purchased death certificates through the health authorities relating to the specific boroughs. Where consent had been withdrawn we recorded the fact of death if known but not the reason. The censoring date was the date of death, the final interview date or the date

when the interview would have taken place for those who were lost to follow-up. For the latter group, deaths were monitored using public sources up to their censoring date. If the reason for loss to follow-up was withdrawal of consent, the reasons for death were not sought unless available as part of the public record. An intermediate censoring date was also created, based on the 36-month interview date. Only deaths that occurred before that date were used when analysing the 36-month data.

A sample size of at least 800 participants was calculated to be adequate to allow modelling of associations between physical and mental illness.¹

Analyses

Descriptive statistics were used to summarise the cohort at baseline and logistic regression was used to estimate associations between outcome and predictor variables.¹⁶⁴

The incidence of depression was described from the raw data and separately by depression at baseline. The incidence rates are minimum rates, as missing time points (non-response) were coded as non-depression incident. Mechanisms of missingness were explored and the analyses were adjusted for variables associated with missing time points (age, ethnicity and cancer). The analysis was conducted under the assumption that data were missing at random.

Data were set up for a discrete-time survival analysis as per Singer and Willett.¹⁶⁵ Discrete-time survival analysis was chosen as the appropriate model to estimate the odds of an event and the time to an event occurring. Discrete-time (as opposed to the more common continuous time) survival analysis was chosen to reflect the sampling design of 6-monthly time intervals. For more information on discrete-time survival analyses please refer to Singer and Willett.¹⁶⁵

The baseline hazard was first modelled as unstructured, thereby allowing the odds of depression incidence to vary freely among time points; however, we chose to adopt a growth curve modelling framework for the odds of becoming depressed over time. This was estimated using Mplus version 7 (Muthén & Muthén, Los Angeles, CA, USA) and in a latent variable framework using robust maximum likelihood. For more information please see Muthén and Masyn.¹⁶⁶ This approach allows for both time-invariant and time-variant predictors to affect both the intercept and the change in odds with time (linear and quadratic terms). The assumption of proportional odds was tested by including time-varying effects of predictors and comparing nested models using the Satorra-Bentler scaled chi-squared difference test.¹⁶⁷ Model development started with an unconstrained 'full' model, with a number of variables included on a theoretical basis and inspired by our baseline paper (see *List of variables tested*). Parameters were tested using chi-squared difference testing and assessment of model fit statistics (Akaike information criterion and Bayesian information criterion), and the model presented is our best fitting constrained model.

List of variables tested

Depression at baseline, history of depression, sex, age, employment status, relationship status, alcohol intake, smoking status, EQ-5D items (problems with mobility/pain, self-care, usual activities, pain/discomfort), SPQ items covering a range of social problems, diabetes, Rose angina questionnaire, cardiac events during the cohort (including MI) and cardiac operations (bypass graft or angioplasty).

Standardised mortality ratios for those aged > 45 years were calculated in relation to the 2011 Office for National Statistics figures for heart disease (*International Classification of Diseases*, 10th edition), by age and sex.¹⁶⁸ Time at risk was assigned to 10-year age bands with a 'lexis' expansion using the `stsplit` command in Stata. Incident rates of mortality were analysed separately using Poisson regression modelling which took into account the time at risk. Covariates were selected to be the same as those considered in the primary analysis of cardiac outcome. An analysis was also performed using the outcome of 'non-cardiovascular deaths' with the same covariates to explore trends for other causes of death.

Results

Recruitment and retention of the study population

Recruitment

Recruitment into the cohort study is shown in *Figure 10*. Sixteen general practices from south London participated in the research programme, and from these practices 803 participants were recruited into the cohort study from the practice-held CHD registers. The study population represented 27% of those eligible to be included in the cohort study.¹⁶⁴

Retention of study population

The average follow-up time for 803 participants (561 men and 242 women) from 16 practices was 2.64 years and the median was 2.94 years; 141 (17.9%) were lost to (complete) follow-up or declined to be interviewed at some point during the 36-month follow-up period. A further 22 (2.8%) died of cardiac causes, 22 (2.8%) from vascular disease and a further 28 (3.64%) died from other causes. *Table 19* shows the reasons for leaving the study prematurely.

Baseline characteristics of the study population

The baseline characteristics of the cohort population have been published in detail.¹⁶⁴ Tables 20–22 show the demographic, social and clinical characteristics of participants. Essentially, this was an older population (average age 71 years), predominantly male (70%), with 87.3% classifying themselves as ‘white’. Black and ethnic minorities made up 13% of participants. As would be expected, the majority were retired (77%). The average length of time since a diagnosis of CHD was made in the GP records was 10 years, and 44% reported ongoing chest pain. Social problems were common, with relationship problems being the most common reported social problem (38%). Levels of disability were also high in this population, with 53% reporting problems with pain or discomfort and 49% with mobility problems.

Table 23 shows that our cohort study population contains approximately equal proportions of those with a completed MI and a current GP diagnosis of ischaemic heart disease with no history of MI. Similarly, equal proportions have and have not received some kind of surgical intervention.

Cardiac status at baseline is shown in Table 24.

Using the short Rose angina questionnaire, just over one-quarter of the cohort report exertional pain, which could indicate angina. Using the more stringent full Rose angina questionnaire criteria, 13.9% are likely to have a clinical diagnosis of angina (grade 1 or 2).

Grade 2 angina (requires pain on the level)	47 (5.9)
Unclassifiable	74 (9.2)

Discussion

A total of 44% of the sample stated that they currently experience chest pain. If this pain reflected just current angina pectoris, this figure would be very high, given that angina typically accounts for 4% of GP consultations and, in community samples of older people in Scotland, rates of angina pectoris using the Rose angina questionnaire are reported as 2.5% for men and 2.7% for women.¹⁶⁹ A meta-analysis of prevalence rates of angina in community samples in 31 countries showed a weighted mean of 5.7% for men and 6.7% for women – the highest rates from any of the countries were 14.4% for men and 15.7% for women.¹⁷⁰ Rates of angina following infarction are reported at 19%¹⁷¹ and there should not be any in the aftermath of successful revascularisation.

In fact, chest pain is commonly reported as a symptom in representative epidemiological studies, along with other types of pain. In one study, 12% of participants reported chest pain, compared with 41% reporting backache and 26% reporting headache.¹⁷² The most common explanatory physical diagnosis for chest pain is oesophageal reflux.^{173,174} There has been one epidemiological study in Australia of those with non-cardiac chest pain.¹⁷⁵ The authors noted that (1) the most common accompanying symptom was heartburn that suggests oesophageal disorder; (2) many did not seek help for it; and (3) quality of life was reduced for those reporting it with.^{175,176} Non-specific chest pain is associated with an increased mortality rate.¹⁷⁷

It has long been recognised that many patients referred for investigation of chest pain have concurrent anxiety and depression syndromes.¹⁷³ Chest pain is indeed a recognised symptom for the diagnosis of a panic attack.¹⁷⁸ Case-level anxiety or depression has been stated to be a contraindication to expensive cardiology investigation, as few patients are found to have coronary disease.¹⁷⁹

Most of the work on the association of chest pain with psychiatric disorders has been carried out in cardiology patients. Our study population is different in that we have recruited our patients from a primary care-based register of CHD patients, some of whom are under the care of cardiologists. To our knowledge, there are no previously published studies on this topic based on GP register patients.

We are mainly reporting on the group identified as 'exertional pain' from the short Rose angina questionnaire, as there is adequate indication from published studies that this symptom is the most prognostically important for future events as described above.¹⁶³ The distribution of the data when classified by the short Rose angina questionnaire data also allows greater power in our analyses, and there are fewer missing responses than when using the long version. Multivariate analyses have been conducted to investigate baseline associations of short Rose classification.

Exertional pain versus non-exertional pain (risk factors)

The next analysis (Table 25) simultaneously compares those with chest pain with those with non-specific pain, and with those with exertional chest pain. Each paired analysis takes into account the third group.

The variables entered were those baseline variables describing cohort members set out in the paper on baseline analyses.¹⁶⁴ They concern sociodemographic status, cardiac variables, self-reported cardiac risk factors, physical disease comorbidity and social problems.

Variables were included in the model if they provided information to an alpha threshold of $p < 0.2$. Variables in the model were age, sex, ethnicity, Index of Multiple Deprivation (IMD) score, smoking status, comorbidity of COPD, depression (positive on the HADS-D scale), anxiety (positive on the HADS-A scale), total number of SPQ social problems and 'How much bodily pain' (i.e. non-specific pain) in the past 4 weeks? (Question 21 on the Short Form Questionnaire 36-items quality-of-life scale.) Only those variables contributing with a significance threshold of $p < 0.05$ are reported above.

For continuous variables (age, IMD score and total SPQ social problems): with every one unit increase in IMD deprivation, the RR of being in the chest pain group compared with the no chest pain group increases by 3% (RR 1.03; $p > 1$).

TABLE 25 Multinomial logistic regression of the Rose classification (short Rose angina questionnaire classification) on sociodemographic and clinical predictors ($n = 626$). Reference group 1: no chest pain

Sociodemographic and clinical predictors	Group 2: chest pain only	Group 3: exertional pain
Variable (adjusted risk ratio)		
IMD score	1.04*	
Depression		
No	Reference	Reference
Yes	3.29*	2.32*
Anxiety		
No	Reference	Reference
Yes	2.96*	2.26*
How much bodily pain?	1.18	1.27*
Comorbidity: COPD		
No		Reference
Yes		1.86
Primary GP coded CHD diagnosis		
MI		Reference
IHD/angina		2.34*
Other		0.74
Total SPQ social problems		1.36*
*, $p = 0.05$. IHD, ischemic heart disease; IMD, Index of Multiple Deprivation.		

For the categorical variables (sex, ethnicity, depression, COPD and primary GP coded CHD diagnosis): for those classified by the HADS as having depression compared with those without HADS depression, the RR of being in the chest pain group was 2.87, and being in the exertional pain group was 2.92, both compared with the no chest pain group.

The analysis in *Table 25* was repeated using the full (long) Rose angina questionnaire classification variables: no pain ($n = 447$), pain in chest ($n = 171$), grade 1 and grade 2 angina ($n = 111$). The results, which are not reported here, were very similar.

Discussion

Notable in the results of this analysis is the absence of any of the cardiac variables or cardiac risk factors that we recorded as associations of chest pain (whether or not the chest pain was exertional) – in particular whether or not there is a history of a revascularisation procedure. The association with GP diagnosis of ischemic heart disease and exertional pain is compatible with the validation criteria of the Rose angina questionnaire. The association with COPD has clinical face validity – sufferers may experience discomfort when they exert themselves.

Depression, anxiety and social factors are the evident associations. The most potent association is the number of social problems rather than any individual social problem. For every additional social problem reported, the risk of exertional pain increases by 36%. Depression and anxiety are both associated with complaints of non-specific and exertional pain – the RR being higher for the exertional pain. Experience of panic and bodily pain remain independently associated with chest pain. Increasing report of bodily pain is associated with increased risk of being in both of the two chest pain categories.

The data from this cohort strongly suggest a psychosocial context for the complaint of chest pain whether or not it is anginal in type. As this is a cross-sectional analysis, direction of causality cannot be assumed. It is possible that having chest pain limits life to the extent that multiple social problems result, for example less social contact.

Chest pain and quality of life

Baseline analysis

The literature suggests that quality of life is impaired many years after MI for those with persisting symptoms,¹⁸⁰ the effect being more marked in younger than older people. The same is reported for those with non-cardiac chest pain.¹⁷⁵ The EQ-5D is used in these analyses as a measure of health-related quality of life, a score can be obtained by summing the response to the five questions asked or from the accompanying visual analogue, in which the respondent makes a judgement of their quality of life now. We have chosen the latter, as one of the five questions asks about anxiety and depression and we wish to examine quality of life separately from mental state so far as is possible.

Examination of associations of baseline European Quality of Life-5 Dimensions visual analogue scale

Quality of life was thus recorded using the EQ-5D questionnaire visual analogue scale (EQ-5D-VAS). To examine the factors associated with quality of life, we used a multiple linear regression model and selected variables from a large pool of sociodemographic and clinical factors. Variables were selected using a stepwise selection procedure that retained all predictors if evidence for their association with the visual analogue scale was lower than $p = 0.2$.

The outcome, as well as all predictors used in this analysis, was collected by self-report questionnaire and at the same time point (baseline), and so this analysis can be seen as an examination into the factors associated with quality of life and, on an exploratory basis, an examination into the potential predictors of quality of life in our cohort. Owing to the positively skewed distribution of the EQ-5D-VAS, non-parametric bootstrapping using 200 replications was used in the analyses.

The results of this analysis are shown in *Table 26–28*.

The data in *Table 27* show high correlation between anxiety and depression scores, and between EQ-5D scores and both. In the latter, high depression anxiety scores (bad) correlate inversely with high EQ-5D scores (good). *Table 28* shows analyses that explore, at baseline, what factors influence the EQ-5D-VAS score in this cohort.

TABLE 26 Description of EQ-5D-VAS at baseline

BMI, body mass index; CABG, coronary artery bypass graft; SE, standard error.

a Item taken from the SF-12.

NotesObservations: $n = 679$.Adjusted $r^2 = 0.255$.Predictors selected using a stepwise selection procedure and retaining all predictors $p < 0.2$. Bootstrapping was used to compute standard errors and CIs owing to the skewed distribution of EQ-5D-VAS. Both bootstrap standard errors and bias-corrected CIs are reported.**Summary of results**

The following variables associated with baseline quality of life:

- Ethnicity: white ethnic group had a 4.74 unit higher score ($p = 0.024$). This is a small standardised effect size (0.1).
- Current smokers: current smokers scored, on average, lower by 5.19 units ($p = 0.022$).
- Exertional chest pain: those with exertional chest pain had a lower quality-of-life score by 3.90 units ($p = 0.020$), a small effect size (0.09).
- Bodily pain: those reporting bodily pain (an item taken from the SF-12) had, on average, a 3.85-point lower score on the EQ-5D-VAS ($p < 0.001$). This was a moderate effect size (0.28).

- Treatment for heart problem: people who had received a treatment for their heart problem in the past had a lower quality-of-life score by -2.75 units ($p = 0.021$). This was a small effect size (0.07).
- Cancer: cancer was associated with lower quality of life by 5.63 points ($p = 0.013$). This was a small effect size (0.1).
- Depression: HADS-D (scoring ≥ 8 on the HADS-D scale) was associated with a 9.71-unit lower quality of life ($p < 0.001$). This was a small effect (0.17).
- Anxiety: HADS-A (score of ≥ 8) was also associated with a lower score on the EQ-5D-VAS scale by 4.8 units ($p = 0.003$). This was a small effect (0.11).

Depression, anxiety and chest pain all impair quality of life at baseline.

Prevalence, incidence and course of depression

Prevalence of depression

The prevalence of depressive and anxiety disorders and the risk factors associated with a depressive disorder at baseline have been presented in detail elsewhere³¹ and will be summarised here. The prevalence of depressive and anxiety disorders in this population at baseline is shown in *Table 29*.

The proportion of the population who had depression recorded as an active problem in GP records at recruitment into the cohort was 7%, whereas 4.6% of the population had an *International Classification of Diseases*, 10th edition, diagnosis of a depressive disorder (mild, moderate or severe) as defined by the Clinical Interview Schedule – Revised (CIS-R). According to the HADS-D scale, 12.8% of the population suffered from a depressive disorder at baseline (i.e. scored > 7 on the depression subscale).

TABLE 29 Mental health status at baseline ($N = 803$)

Mental health status	<i>n</i> (%)
GP diagnosis of depression	56 (7.0)
GP diagnosis of anxiety	95 (11.8)
Depression and anxiety by CIS-R	
No disorder	654 (81.4)
Severe depressive episode	17 (2.1)
Moderate depressive episode	14 (1.7)
Mild depressive episode	23 (2.9)
Panic disorder	4 (0.5)
Generalised anxiety disorder	25 (3.1)
Mixed anxiety and depression	66 (8.2)
HADS scores	
Mean depression score (SD)	3.34 (3.5)
Depression score of ≥ 8	103 (12.8)
Mean anxiety score (SD)	4.97 (4.5)
Anxiety score of ≥ 8	199 (24.8)
CIS-R, Clinical Interview Schedule – Revised.	

The statistically significant associations between predictor variables and CIS-R-defined depression at baseline fell into three domains: living alone, disability and pain, and age (problems with living alone: adjusted OR for a CIS-R diagnosis of mild, moderate or severe depressive episode 5.49, 95% CI 2.11 to 13.40; $p < 0.001$; experiencing chest pain: adjusted OR for a CIS-R diagnosis of mild, moderate or severe depressive episode 3.27, 95% CI 1.58 to 6.76; $p = 0.001$; being disabled by pain or discomfort: adjusted OR for a CIS-R diagnosis of mild, moderate or severe depressive episode 3.39, 95% CI 1.42 to 8.10; $p < 0.006$; having problems carrying out usual activities: adjusted OR for a CIS-R diagnosis of mild, moderate or severe depressive episode 3.71, 95% CI 1.93 to 7.14; $p < 0.001$; and age: adjusted OR per year for a CIS-R diagnosis of mild, moderate or severe depressive episode 0.95, 95% CI 0.92 to 0.98; $p < 0.001$) (see Walters *et al.*¹⁶⁴). Chest pain was significantly associated with depression independently of other pains and discomfort.

Participants had an increased odds of having a GP-recorded diagnosis of depression if they reported problems with close relationships (adjusted OR for a GP diagnosis of depression 2.51, 95% CI 1.40 to 4.52; $p = 0.002$), reported having diabetes mellitus (adjusted OR for a GP diagnosis of depression 2.01, 95% CI 1.11 to 3.63; $p = 0.02$), were disabled by pain and discomfort (adjusted OR for a GP diagnosis of depression 1.95, 95% CI 1.04 to 3.68, $p = 0.037$), or were female (adjusted OR for a GP diagnosis of depression 1.88, 95% CI 1.04 to 3.37; $p = 0.035$) (see Walters *et al.*¹⁶⁴).

Incidence of depression and risk factors for incident depression

The incidence risk of developing a depressive disorder (as defined by scoring ≥ 8 on the HADS-D subscale) is shown in Table 30. The proportion of new cases of depression was similar at each time point for those

TABLE 30 Risk of a new depressive disorder during each 6-month time point

a As defined by a HADS-D subscale score of ≥ 8 .

who were not depressed at baseline. However, the proportion of incident cases of depression decreased across time points for those who were depressed at baseline. The cohort followed participants for a total 1942.3 years at risk. During this period there were 240 incident cases of depression giving an incident rate ratio of 123.6 per 1000 person-years at risk.

The risk factors associated with the incidence of depression are shown in *Table 31*. The strongest predictor of incident depression was having had a documented MI at some point before the incident depression. Other predictors of incident depression were: suffering with depression at baseline or having a past history of depression, self-reported exertional chest pain, problems with disability and living alone.

[Exertional pain was initially considered as a possible type 3 variable. However, in the final model it was better treated as a time-invariant (baseline only) predictor because of uncertainties in the longitudinal data recording. It was not always possible to establish the time sequence of the incidence of pain and depression and there were a large number of missing values, which greatly reduced the sample size.]

The course of depression in cohort participants is described in *Table 32*.

TABLE 31 Discrete-time survival model for predictors of incident depression (as defined by a HADS-D subscale score of ≥ 8)

Predictors	OR	Logit-hazard function	SE	Estimate/SE	p-value

SE, standard error.

a Time-invariant predictors with a time invariant effect denote predictors that had a constant effect on the incidence of depression (i.e. proportional).

b Time-invariant predictors with a time varying effect denote variables that had an initial effect of changing the odds of becoming depression incident but this effect was not proportional and changes with time.

c Time-varying predictors with a time invariant effect denote predictors that change with time (i.e. a person may not experience a MI until 30 months). The effect of the predictor is said to be time invariant, as whenever the variable changes (e.g. 6 months or 30 months), it will have the same effect.

TABLE 32 Patterns of depression from baseline to 36 months

Patterns of depression	No missing values, n (%)	Missing values during follow-up, n (%)	Missing at follow-up, n (%)	Total, n (%)
Depression at baseline	54 (10.8)	9 (13.0)	40 (17.4)	103 (12.9)
Always depressed	18 (33.3)	5 (55.6)	21 (52.5)	44 (42.7)
No depression at final follow-up	19 (35.2)	3 (33.3)	14 (35.0)	36 (35)
Improved then depressed at final follow-up	17 (31.5)	1 (11.1)	5 (12.5)	23 (22.3)
No depression at baseline	446 (80.2)	60 (87.0)	190 (82.6)	696 (87.1)
No depression at any point	338 (75.8)	45 (75.0)	149 (78.4)	532 (76.4)
Developed depression at final follow-up	51 (11.4)	9 (15.0)	24 (12.6)	84 (12.1)
Developed depression, not at final follow-up	57 (12.8)	6 (10.0)	17 (8.9)	80 (11.5)
Total	500 (62.6)	69 (8.6)	230 (28.8)	799

Of the 12.9% of participants depressed at baseline, 42.7% remained depressed throughout the 36-month follow-up period. Only 35% were not depressed at final follow-up. Of those not depressed at baseline, 23.6% developed depression at some point over the follow-up period.

The incidence and effect of depression and anxiety on cardiac outcomes and mortality

The incidence of cardiac outcomes is reported in two ways – first, the incidence of cardiac events over the follow-up period (and the effect of depression and anxiety) and, second, the continuing reporting of chest pain over that same period.

Table 33 shows the incidence of cardiac events over the 36-month follow-up. There were 44 total deaths that had a cardiovascular cause. Sixteen patients in the cohort had a MI during the follow-up period.

Table 34 shows the percentage of cardiac outcomes that were related to depression and anxiety. Although our initial analysis was done with depression, we found that for every cardiac outcome anxiety was more strongly related, especially in MI and cardiovascular death.

Table 35 shows the predictors of cardiac outcome with 'no chest pain' as comparator.

TABLE 33 Incidence of cardiac interventions, MI and cardiovascular deaths up to 36-month follow-up

Time point (months)	Bypass graft or angioplasty, n (%)	MI, n (%)	Cardiovascular death, n (%)	Any
Baseline	12 (63.2)	7 (36.8)	0 (0.0)	19

Discussion

In terms of predictors of cardiac outcome status, chest pain and exertional chest pain were not associated with baseline depression status but were statistically significantly associated with baseline anxiety. There were no associations between attendance at a rapid access cardiac clinic for a cardiac reason and either baseline depression or anxiety.

There was no evidence of an association between baseline depression and having a MI or dying from a cardiac cause, but there was a statistically significant association with baseline anxiety and having a MI or dying from a cardiac cause. Rose angina questionnaire categories for chest pain at baseline were significantly and strongly associated with subsequent chest pain and exertional chest pain, especially the latter, and in the direction that would be expected, that is, both were associated with all cardiac outcome status compared with no chest pain with exertional chest pain having a stronger association with cardiac status (apart from attendance at a rapid access cardiac clinic) than chest pain. Women have an increased risk of chest pain and exertional pain (but no evidence for higher risk of other cardiac outcomes). Age was a significant predictor only of MI/death. The effect of adding covariates to an unadjusted model, leading to the full model reported above, is shown in *Table 36*.

Sensitivity analyses

General practitioner practice was also included in the model as a sensitivity analysis as the practices were situated in areas with different sociodemographic characteristics and also had varying levels of loss to follow-up. The results did not differ significantly from the original model, apart from the exertional chest pain outcome, in which depression and anxiety had similar relative risk ratios (RRRs), both of which were significant (depression: RRR 1.702, 95% CI 1.025 to 2.827; $p = 0.040$; anxiety: RRR 1.573, 95% CI 1.027 to 2.411; $p = 0.037$).

TABLE 36 Effect of adjusting for confounders on association between depression and cardiac outcomes (relative risk ratios compared with no chest pain)

Model	Chest pain	Exertional chest pain	Rapid access	Intervention	MI/death
(a) Unadjusted	2.557**	3.729**	2.932**	2.907**	1.030
(b) Adjusted for age, sex, ethnic group	2.357**	3.363**	2.688**	2.430**	1.378
(c) As (b) + Rose category at baseline	1.951*	2.231**	1.892*	1.592	1.177
(d) As (c) + anxiety at baseline	1.353	1.627*	1.449	1.910	0.587

*, $p=0.1$; **, $p=0.05$.
MI/death were combined, as there were too few instances for separate analysis.

The baseline number of comorbid medical illnesses and social problems as measured by the SPQ was added to the model. Depression was now no longer significant for chest pain (RRR 1.177, 95% CI 0.650 to 2.130; $p=0.591$), although anxiety remained significant (RRR 1.730, 95% CI 1.132 to 2.643; $p=0.011$). Total number of social problems was also related to chest pain ($p=0.001$), but not the number of comorbidities. In terms of exertional chest pain, in this model, depression was no longer statistically significant (RRR 1.424, 95% CI 0.560 to 2.373; $p=0.174$) although, again, anxiety remained statistically significant (RRR 1.600, 95% CI 1.059 to 2.413; $p=0.026$). There was no change in associations for rapid access chest clinic or for cardiac interventions (neither significant), but social problems were significant for chest pain and exertional chest pain ($p=0.001$ for both) and for cardiac interventions ($p=0.005$), but not for other outcomes.

Two alternative definitions of depression were analysed:

1. Depression in the 6 months before the index cardiac event. The results of this analysis were similar to the main model, except that both depression and anxiety were statistically significantly associated with exertional chest pain (depression: RRR 1.85, 95% CI 1.291 to 2.663; $p=0.001$; anxiety: RRR 1.867, 95% CI 1.349 to 2.585; $p<0.001$). For other outcomes, the model could not be fitted owing to small sample sizes.
2. Cumulative burden of depression using the sum of follow-up periods, occurring before the index cardiac outcome, in which the patient had been depressed. Chest pain and exertional chest pain were both associated with depression and anxiety (depression: RRR 1.217, 95% CI 1.000 to 1.482; $p=0.05$; anxiety: RRR 1.239, 95% CI 1.041 to 1.474; $p=0.016$). However, other outcomes were similar to the main model except that cumulative anxiety was associated with attendance at a rapid access chest clinic (RRR 1.350, 95% CI 1.059 to 1.722; $p=0.015$).

Redefining the cardiac outcome with rapid access chest clinic combined with any other interventions did not show any association with baseline depression or anxiety.

Mortality

There were 72 deaths altogether, of which 22 were from cardiac disease, 22 from vascular disease, 16 from cancer and eight were attributable to other causes; in four cases, the cause of death was not ascertainable. Of the 22 cardiac deaths, 14 were of men (2.5% of 561) and eight of women (3.3% of 242). Incidence rates of cardiac death were 12.7 per 1000 person-years for men and 9.3 per 1000 person-years for women. Standardised mortality ratios compared with the general population were 1.13 (95% CI 0.62 to 1.90) and 1.87 (95% CI 0.81 to 3.70), for men and women, respectively.

Table 37 shows a Poisson regression model for the rates of cardiovascular deaths. Only risk ratios for increasing age and a higher baseline anxiety were significant at $p=0.05$. A sensitivity analysis using the CIS-R definition of depression and anxiety was similar, except that the risk ratio for depression was

TABLE 37 Baseline associations with cardiovascular mortality

increased to 1.260 (95% CI 0.274 to 5.796; $p = 0.766$) and that for anxiety decreased (risk ratio 2.001, 95% CI 0.694 to 5.774, $p = 0.199$) and was no longer significant.

Table 38 shows a Poisson regression model for the rates of non-cardiovascular deaths. Only RRs for increasing age, male sex and higher baseline total comorbidities were significant at $p = 0.05$.

The types and course of chest pain, and predictors of chest pain as an outcome

The effect of depression on continuing chest pain

This next series of analyses use data from the five-wave follow-up. We report on the frequency of cardiac events, the persistence of chest pain reported by respondents and the predictive power of depression and other psychosocial factors.

Chest pain type and frequency of report

As shown in Table 39, the amount of chest pain is reported, ranging from 0 to 100%, of the occasions when patients were interviewed using the Rose angina questionnaire. These proportions became the outcome variable to contrast with baseline predictors between those with no chest pain and those with non-exertional pain only.

TABLE 38 Baseline associations with non-cardiovascular mortality

	Adjusted RR	95% CI	p-value
Female	0.227	0.065 to 0.796	0.021

BMI, body mass index.

^a Unable to compute owing to limited data.**TABLE 39** Frequency of chest pain (both exertional and non-exertional) reported across the follow-up period

	Full sample (N = 803), n (%)
No chest pain	345 (45)
Non-exertional pain only	103 (14)
1–25%	90 (12)
26–50%	98 (13)
51–75%	43 (6)
76–100%	82 (11)
Total	761 (91)

In contrast to *Table 39*, which takes into account the whole cohort, subsequent analyses report on those who remained under follow-up who did not experience any of the events mentioned above. In addition, only those who had, at most, two missing chest pain responses out of the five possible over the follow-up period were included. Those with more than two missing responses were excluded. (Sensitivity analysis was carried out restricting it to one or fewer missing responses, and no differences were found, thus we selected this analysis, which includes a larger portion of the sample.) These two exclusions reduced the sample for analysis to $n = 568$. Baseline depression and anxiety scores were examined separately, and then quality of life, as measured by the EQ-5D-VAS, was entered into the analysis.

Predictors of non-exertional pain

Females and those with asthma comorbidity were most at risk of reporting non-exertional chest pain (*Tables 40* and *41*). Shorter amount of time on the GP CHD register is also predictive. Anxiety and depression, counterintuitively, do not have an effect. The addition of the quality-of-life measure does produce a significant finding, with a lower score being predictive of more pain report.

Exertional pain

The situation with exertional pain is quite different (*Tables 42* and *43*). Exertional pain reported at baseline had a massive effect in predicting subsequent reports of chest pain, as did, to a lesser extent, non-exertional pain. Depression and anxiety each had an additional effect on baseline pain. The length of time on the register was predictive, but in the opposite direction to non-exertional pain, meaning the longer time spent on the register, the more likely they were to report exertional pain. Older age was a weak risk factor. Addition of the quality-of-life measure eliminated the effect of depression, and weakened that of anxiety.

TABLE 40 Effect of anxiety alone on non-exertional chest pain and with inclusion of EQ-5D-VAS in patients with two or fewer missing time points

Economic analysis of the UPBEAT-UK programme

Objectives

To:

1. assess the long-term costs of care for a sample of patients with CHD and comorbid (a) baseline, and (b) subsequent depression compared with those without comorbid depression
2. identify predictors of these costs.

Methods

Health-care utilisation and costs

The primary measures for the economic analysis were health-care utilisation and total health-care and societal costs. Medical and informal (i.e. family care) resource utilisation was assessed using a questionnaire, the Client Service Receipt Inventory, developed by members of the Centre for the Economics of Mental and Physical Health.¹²⁷ The questionnaire is frequently used in mental and physical care evaluations. Medical utilisation included the number of contacts with hospital and community services and (where appropriate) the length of these contacts and the duration of stay for inpatient care. Hospital service utilisation consisted of outpatient, inpatient, A&E and day hospital visits. Community services mainly included contacts with GPs, practice and district nurses, other medical professionals (psychiatrist, other community-based doctor, community mental health nurse, health visitor, other nurse, psychologist, counsellor, occupational therapist, physiotherapist, 'alternative' medicine or therapy, other therapist) and care professionals (social worker, housing worker, home help/home care worker, care attendant, community support worker, voluntary worker, day centre/drop-in/social club, any other community-based service). Informal care involved assistance in daily activities by family members, relatives or friends (i.e. personal or child care, help in/around and outside the house) and was measured as the average weekly hours spent with the patient specifically because of their health problems.

Data were collected every 6 months for a period of 3 years between September 2007 and September 2012.

Total costs were calculated from both a health-care payer's and a wider societal perspective, by multiplying the estimated resource use by the corresponding unit cost. Unit costs were applied to service-use data using the NHS Reference Costs for 2011–12¹⁸¹ and the 2012 Unit Costs of Health and Social Care.¹²⁹ The unit cost of a home care worker was used as a proxy for costing informal care. Wherever necessary, costs were inflated to 2012 prices using the inflation indices for hospital and community health services.¹²⁹ All costs were expressed in pounds sterling (GBP).

Indirect costs of productivity loss due to CHD and comorbid depression were not included in the analysis because of incomplete data on sickness absence from work, occupation and status or mode of employment (i.e. full time or part time). However, the average age was 71 years and most participants were retired. Therefore, productivity loss is not likely to be a major consideration.

Medication use was self-reported and was recorded for baseline only (for the past 6 months).

Missing values

Across the study period (six follow-ups), some data (overall approximately 15% of data items) on health-care utilisation were missing, mainly representing the missing number and/or duration of contacts. The approach adopted to handle the missing data was imputation by the mean values of the respective variables at each time point. Owing to the large sample size and the fact that total outcomes are presented at a mean level, it was decided to use the mean instead of median imputation. In three observations where the number and/or duration of contacts were reported but the type of service was missing, the imputed value was assumed to be the most frequently used service across the study period.

Sample characteristics

Differences in sociodemographic variables between CHD patients with/without comorbid baseline depression were analysed using a two-sided *t*-test and chi-squared test. Depression status was measured by the HADS-D at baseline and at each follow-up point. Patients were classified into depressed and non-depressed, using a cut-off score of ≥ 8 for possible depression.¹¹⁴ At baseline, 13% of patients had depression.

Sociodemographic characteristics of the sample are shown in *Table 44*. Approximately two-thirds were male in both groups and the average age was 66 years and 71 years for the depressed and the non-depressed group, respectively. The majority of patients were married and retired, with only a small proportion (< 5%) cohabiting. In the non-depressed group, 53% received > 11 years of education while a similar proportion in the depressed group received < 10 years of education. Approximately half of either group were ex-smokers and consumed, on average, between 0 and 10 units of alcohol per week. The mean IMD score was 20 and 23, for the non-depressed and depressed group, respectively. The vast majority of the depressed patients reported chest pain, while most of the non-depressed patients did not have chest pain. Both groups had an average number of two additional comorbidities, with the most frequent ones being hypertension and diabetes. Approximately 65% of patients had depression when assessed by the CIS-R instrument. It is noticeable that approximately 80% of the depressed patients also had anxiety when measured by the HADS-A. Most of the differences were statistically significant at a 10% level (see *Table 44*).

a HADS-D score of ≥ 8 .

Statistical analyses

Statistical analyses were carried out using Stata version 11. Regression analysis was used to estimate mean differences in service use and costs between groups. Baseline and follow-up costs were used as the dependent variables and the group identifier as the independent variable. To estimate whether or not the difference in costs between depressed and non-depressed patients was present at each time point, the HADS-D status was also assessed at consecutive follow-up times (*Figure 11*).

Sociodemographic and clinical baseline variables were tested for significance using simple ordinary least squares regression models. Each variable was regressed on the cumulative 3-year hospital care costs, community care costs, informal care costs, total health-care costs and total societal costs. Those variables with statistical significance at the 10% level ($p < 0.10$) in at least one of the above mentioned dependent variables were included in the final multivariate model to identify predictors of costs (*Table 45*). Certain other variables that were of interest, although not statistically significant in the first stage, were also included in the final models. Of the statistically significant variables, those with high numbers of missing values were excluded from the final models. The remaining variables were checked for correlation and those that were highly correlated ($r \geq 0.7$) with each other were removed, one at a time, from the model. Two models were constructed using the cumulative health-care and societal costs as the dependent variables. The models included the following baseline covariates: sex, ethnicity, relationship status, age at referral, health literacy status, years in education, family history of depression or cardiac problems, smoking status, average units of alcohol per week, the body mass index score, number of CHD risk factors, depressive disorder assessed by the CIS-R, currently being treated for depression, anxiety status measured by the HADS, the IMD score, housing, working or financial problems, social contact and relationship problems, currently active comorbidities such as diabetes, arthritis, cancer, asthma, hypertension, COPD and chronic kidney disease. The models were also adjusted for informal care costs and total health-care costs at baseline. Approximately 100 observations had missing data on the health literacy variable. Thus, two additional models including all the above covariates except the health literacy variable were also run. To produce a more parsimonious model that aids interpretation, the backward elimination stepwise method was used. This method involved starting with all independent variables and then sequentially removing variables with the highest p -values until only those with p -values < 0.1 were included.

It is commonly known that health-care data often violate the assumptions underlying ordinary least squares. Therefore, the models were run to test for the assumptions of normality and homoscedasticity of residuals. Both assumptions were violated and generalised linear models were used. The use of log transformation is common practice for dealing with skewed data, such as costs. However, log-scale results are of little interest in decision-making, while actual values (i.e. GBPs) are meaningful. Generalised linear models overcome the shortcomings of (log) ordinary least squares using the original scale of costs.¹⁸² To use generalised linear models, the distribution of cost data and a function that specifies the relationship between the mean and the linear specification of the covariates (the so-called link function) must be specified.¹⁸² The appropriate distribution of costs was identified by implementing the modified Park test.¹⁸³ The gamma distribution, with a log-link function, was applied to the final model. The log-link function means that the value of the exponentiated coefficients is interpreted as proportional changes of the 3-year total health-care and societal costs (*Tables 46–49*).

Results

Health-care utilisation

Tables 50 and 51 show the cumulative resource use by depression status. Depressed patients utilised more health-care resources than non-depressed patients during the 3-year study period (87.6 vs. 59 total health-care contacts; 95% CI 5.4 to 51.8). In particular, 41% of the depressed patients used the A&E department, compared with 33% of the non-depressed patients, but the average number of attendances was 0.3 lower in the depressed group than in the non-depressed group. However, the mean number of attendances was higher for the depressed patients in all periods except the last year. The differences were not statistically significant.

TABLE 50 Cumulative resource use by type of service and by group for service users at 36 months

1–3 years: service users	No depression (<i>N</i> = 696)			Depression (<i>N</i> = 103)			Difference, mean duration (minutes) (95% CI)

TABLE 51 Grouped cumulative resource use for service users at 36 months

1–3 years: service users	No depression (N = 696)		Depression (N = 103)		Difference, mean (95% CI)
	n (%)	Mean (SD)	n (%)	Mean (SD)	
Hospital care contacts	162 (23)	7.5 (14.1)	30 (29)	10.0 (21.0)	2.5 (–3.5 to 8.5)
Community care contacts	210 (30)	15.6 (52.3)	32 (31)	44.1 (138.2)	28.5 (2.5 to 54.6)
Primary care contacts (includes contacts to GPs, practice and district nurses)	655 (94)	20.9 (26.3)	93 (90)	22.2 (21.3)	1.3 (–4.3 to 6.9)
Secondary care contacts (includes hospital care and contacts to other medical or care professionals/specialists).	630 (91)	40.0 (95.7)	91 (88)	67.9 (128.5)	27.9 (5.8 to 50.0)
Total health-care contacts	658 (95)	59.0 (102.7)	94 (91)	87.6 (134.5)	28.6 (5.4 to 51.8)

Patients with depression used inpatient care more and stayed in hospital significantly longer (7.8 days, 95% CI 0 to 15.6 days) than patients without depression. Approximately 5% of the patients were hospitalised for CHD reasons (1% of those had depressive symptoms). Nearly 80% of patients in both groups used outpatient care, with the depressed group using it more intensively (17.6 vs. 12 visits, 95% 0.7 to 10.9 visits). Patients in both groups made similar use of primary care, which included contacts with GPs, practice and district nurses, with the depressed group having a slightly higher frequency of contact. The mean duration of contacts with GPs and PNs was slightly, but not significantly, higher (1.4 minutes per patient) for the depressed patients than for the non-depressed patients. Patients with depression tended to spend approximately 5 minutes more with their GPs than non-depressed patients. Overall, secondary care, which included hospital care and care provided by other medical and care professionals (e.g. psychiatrists, psychologists, other community-based doctors, mental health nurses, social workers, housing workers and care attendants), was used more by the depressed group, with a significant difference of 27.9 contacts (95% CI 5.8 to 50 contracts) compared with the non-depressed group.

Resource use (by time point)

It was found that informal care was utilised more (54% vs. 30%) and more intensively (19.6 vs. 17.7 average hours per week per patient) by the depressed patients than by the non-depressed ones. Information on resource use by type of service and by group at each time point, separately, is given in Tables 52–58.

TABLE 52 Resource use by type of service and by group for service users at baseline

						48.6 (–39.8 to 137.1)

Costs

The cumulative costs for the 3-year study period are shown in *Tables 59* and *60*. Costs by type of service and by patient group at each time point for service users only (i.e. excluding those with zero costs) and for the whole sample are given in *Tables 61–67* and *Tables 68–74*, respectively. In almost all types of service, patients with depression incurred higher costs than patients without depression. The difference was statistically significant for costs of outpatient services and contacts with other medical professionals as well as for total costs. The aggregated 3-year costs for service users were significantly higher for the depressed group than for the non-depressed group, by approximately £4000 (see *Table 59*). The highest costs were for inpatient care across the study period (*Figure 12*). At baseline the non-depressed group incurred higher inpatient care costs per patient than the depressed group (–£1739, 95% CI –£3790 to £312). However, baseline costs were not included in the calculation of the aggregate costs because the estimates referred to the 6-month period prior to the study initiation. In all other follow-ups, there was a positive difference of approximately £3000 in inpatient care costs between patients with and without depression, except in the 36-month follow-up, in which case the difference remained positive but at a lower level (£1534, 95% CI –£1772 to £4840) (see *Tables 61–67*).

A&E attendances	15 (82)	14 (39)	0 (–17 to 16)
Day hospital attendances	28 (136)	40 (204)	12 (–20 to 44)
Inpatient stays	361 (1668)	772 (4347)	411 (–98 to 919)
Outpatient visits	286 (647)	721 (2434)	435 (182 to 688)
GP visits	77 (166)	206 (1019)	129 (32 to 227)
PN visits	16 (101)	14 (43)	–2 (–22 to 18)
District nurse visits	6 (52)	29 (195)	24 (3 to 44)
Other medical professional	12 (66)	35 (220)	22 (–1 to 46)
Other care professional	41 (260)	430 (1947)	388 (205 to 571)
Total health-care costs	842 (1884)	2261 (5997)	1418 (765 to 2071)
Informal care (hours per week)	20 (105)	57 (192)	37 (10 to 63)
Total societal costs	862 (1895)	2317 (6014)	1455 (799 to 2110)

FIGURE 12 Hospital services costs per patient (£, in 2011–12 prices) by cost category and by group for service users over time.

The vast majority of patients in both groups received outpatient care, and care from GPs and PNs. Outpatient care costs per patient were higher for patients with depression during the study period and significantly higher at 12, 24, 30 and 36 months, at around double the costs of the non-depressed group. However, the number of people who utilised the services was similar for both groups at each time period. Only a few patients used day hospital services at each time point; however, the costs incurred were high for both groups. This can be attributed to the high cost of some services, such as cataract operation. Average community care costs per patient were higher by £475 for patients with depression than for those without depression, and the difference was statistically significant (95% CI £66 to £883). Community costs and total health-care costs are shown in *Figures 13–16*. None of the differences in informal care costs during the study period was statistically significant. Societal costs are shown in *Figures 17–21*. Indirect costs included informal care, which was similar between groups, with slightly higher costs incurred by the depressed group (difference £43, 95% CI –£164 to £251), especially during the last three follow-up periods (see *Figures 16 and 18*).

Predictors of costs

Tables 46–49 show the output of the four generalised linear models, having accounted for the impact of depression status on costs by using the depressive disorder assessed by the CIS-R as an input variable. The results reveal that health literacy had a significant negative impact on total costs from the health-care perspective. It would decrease costs by approximately 40%. From both the health-care and societal perspective, ethnicity was significantly associated with total costs. More specifically, being Asian, black or an ethnicity other than white is predicted to reduce costs by approximately 45%. Similarly, higher costs were associated with the prevalence of depressive disorder (measure by the CIS-R), with housing and relationship problems, and with currently suffering from cancer.

When the health literacy variable was excluded from the first two models, health-care and societal costs were shown to be significantly and positively associated with having an additional comorbidity other than cancer, and this included chronic kidney disease. Another new factor that was present in these models was reported chest pain, based on responses to the Rose angina questionnaire for angina. The association this had with costs was positive and the magnitude was similar (+23%) from both perspectives. It is notable that smoking status is not now a significant predictor of total costs. Total health-care costs at baseline are predicted not to have any impact on the cumulative health-care or societal costs in any of the four models.

Discussion

The aim of the economic analysis was to estimate the cumulative health-care utilisation and costs of patients with cardiovascular heart disease with and without baseline and subsequent depressive symptoms. The cumulative cost per patient incurred by depressed patients was approximately double the cost incurred by non-depressed patients during the 3-year study period. Overall, inpatient care services dominated costs at baseline and follow-up, while the majority of patients in both groups received outpatient care and care from GPs and PNs.

Across the study period, total costs were increasing, except in the second half of the second year, when they declined dramatically (see *Figure 21*). Differences in costs between depressed and non-depressed patients were statistically significant at almost all time points during the study period. Statistically significant predictors of higher societal costs were depressive disorder (CIS-R), white ethnicity, housing problems, relationship problems, having reported cancer as an additional comorbidity and baseline health-care costs. The prevalence of depressive disorder measured by the CIS-R instrument predicted increases in total costs by approximately 50% in all four multivariate models. Inadequate health literacy was associated with reduced health-care cost and this may reflect poor access to care for this group.

There are several reasons why costs might have been under- or overestimated in this economic analysis. With regard to direct costs, medication costs were not taken into account because such data (self-reported) were available at baseline only. However, some patients were being treated for conspicuous depression and other comorbidities during the study. Although this is a limitation, antidepressant treatment is generally inexpensive, given that the most frequently used drugs are 'off patent'. Another limitation is that indirect costs included only informal care. The high level of missing data in variables related to employment status and sickness absence made it impossible to calculate productivity losses, which is a very important component of indirect costs. Finally, the subgroup analysis was based on depression status as assessed by the HADS score.

Overall, the results could be considered as robust, as data on the important variables for this economic analysis (e.g. service use) were mostly complete, with relatively few having extensive missing data. Further analyses could consider the patterns of depression, examining the varying cost among the different patterns of depression and anxiety. Other future work could look at the economic impact of comorbid depression as a disorder rather than as a symptom-based condition. Similarly, the examination of the relationship between anxiety and costs would be of interest, considering that the majority of patients in the depressed group of this analysis also presented symptomatic anxiety (HADS-A). These findings could drive further research to investigating the excess cost of depression (and/or anxiety) in this patient group by conducting modelling studies on diagnostic and therapeutic approaches that might help to improve health-care outcomes and reduce total costs.

Chapter 6 Summary of the UPBEAT-UK programme

Introduction

This chapter discusses the overall findings of the entire UPBEAT-UK programme and discusses to what extent and how the combined findings from the inter-related work packages have worked synergistically and added to current knowledge about the associations between depression and CHD, and best approaches to manage people with CHD, chest pain and depressed mood.

This is the first time, to our knowledge, that a programme of inter-related work has been conducted with a broad range of people with varying levels of CHD, chest pain and depression/anxiety over 3 years in 33 south London general practices. At the same time, this location is a limitation when it comes to generalising to the country as a whole, as indicated by the lower prevalence of CHD (see *Chapter 1, Patient and public involvement*). It is also the first time, to our knowledge, that the perceptions of users and primary care professionals have been combined to create a new nurse-led form of PC comprising elements of case management and self-management theory for CHD register patients with chest pain and depression.

Most previous research on CHD and depression has been conducted with people who are immediately post cardiac event (usually MI) and who are being seen mainly in secondary care settings. The unique feature of the UPBEAT-UK programme was that we have been able to look at all new incident cardiac events and new incident depression over 3 years in a GP-registered CHD population and examine the factors predicting both cardiac and depressive outcomes. For all four work packages there is, of course, a limitation in generalisation because these were essentially volunteer practices.

In this chapter, we will discuss the combined achievements of the UPBEAT-UK programme and the implications for everyday general practice. It is striking that there is little in the way of available current national guidance for the management of CHD patients with chest pain and depression/anxiety. Existing guidelines tend to either be very non-specific or concern only one condition. However, many older patients have multiple conditions and require complex care pathways.

First, we will summarise the most important findings, which have been described and discussed in each previous chapter.

Overall, we consider the project to have been successful. The main findings were (1) that a much larger trial than we had anticipated would be needed to estimate to what extent the preference-led intervention we developed will be successful in treating depression in CHD patients in primary care; (2) an intervention that would deal with anxiety as well will perhaps improve outcomes; (3) the current primary care practice setting, with the many competing agendas and the generally limited skill levels, may not yet be geared towards delivering the type of integrated care that many of these patients need; and (4) perhaps psychological services such as IAPT are better placed to deliver such care. An IAPT trial seems to be the way forward.

Work package 1

The literature review and metasynthesis of existing literature was conducted at the very beginning of the programme in 2007/8, as this was necessary before we could conduct the qualitative study of professionals. The findings of the review have been published³¹ and have since been highly cited by other authors. It is likely that, since we conducted this review, further relevant research has been published and a future review should include this.

At the beginning of the programme we were unable to identify previous relevant work. We found several papers on depression in primary care but none on CHD, chest pain and depression in primary care.

The qualitative study with GPs and PNs also highlighted the paucity of research or guidelines on how best to manage people with CHD complaining of non-acute chest pain and depression. Consequently, our GP and nurse respondents had no guidance to cite and felt relatively untrained and ill-equipped in this area. In addition, while being very well aware of the frequent concurrence of social problems, they were unsure of what assistance may have been available. With some notable exceptions, GPs and PNs were unsure of their role in managing social problems.

Work package 2

The most striking finding of the qualitative study with patients was that there was such a breadth of 'understandable' psychosocial losses that were described by participants. This then highlighted an immediate mismatch between described user experience and the lack of relevant confidence and skills in the main primary care work force.

Work package 1 and 2 indicated the complexities involved with helping patients to try and improve coping with chronic physical illness and depression in a generalist environment. UK primary care, as busy as it is, is not easily geared towards providing this type of care.

This type of mismatch is likely to militate against full and frank discussion of such issues in every day practice. This, combined with a climate of reactive rather than proactive primary care, provided by increasing numbers of GP-salaried assistants as part of the move away from 'named' professional care, would make it more likely that a 'collusion of anonymity' could occur.¹⁸⁴

Work package 3

Our pilot RCT findings have coincided with a new national policy from the Department of Health that all older patients with long-term conditions should now have a 'named GP' responsible for their personalised case management.¹⁸⁵ We have shown an indication from our small pilot study that a named nurse providing PC combining elements of case management and self-management theory in which patient preference is prioritised appears to enhance both patients' sense of self-efficacy and reduce the self-reporting of chest pain.

In testing the feasibility, acceptability and potential impact of named nurse PC, we have demonstrated that it is acceptable to patients – even if largely by short yet frequent telephone contact, which can be done in a reasonable amount of time – and it is potentially cost-effective, not least if it reduces reported chest pain and potentially attendance at a rapid access chest pain clinic or a 999 call-out and transfer by an ambulance to A&E for further tests.

We used a pilot RCT design¹⁸⁶ to assess the likely benefits and harms of named nurse PC to allow inferences about the possible causal effects of our new intervention. The MRC framework³⁰ recommends RCTs early in the development and testing of complex interventions. For pilot studies such as ours it has been suggested that the analysis should mainly be descriptive or focus on the CI estimates.¹⁸⁷ Pilot studies are described by Arain *et al.*¹⁸⁸ as a smaller version of a main study, to ensure components of the main study work well. They are 'focused on the processes of the main study' such as 'recruitment, randomisation, treatment, and follow-up'. Pilot studies can be run as the first phase of the main study and results can be included in the overall analysis.

Overall the UPBEAT-UK pilot RCT aimed to:

1. identify whether or not UPBEAT-UK nurse personalised case management is feasible and acceptable, and determine any necessary modifications
2. test procedures for a potential future definitive RCT, especially in relation to eligibility criteria, randomisation procedures, allocation processes, and recruitment and retention rates
3. test approaches to assessing fidelity, process evaluation and outcome evaluation, to inform the design of a future potential definitive RCT including choice of primary and secondary outcome measures, and sample size calculation.

The UPBEAT-UK pilot RCT also needed to establish feasibility of the new nurse-led PC, that is, rigorously examine the potential usefulness and acceptability of the intervention and estimate relevant parameters for the evaluation strategy to inform a future definitive RCT.¹⁸⁸ Often there is no clear distinction in the literature between pilot and feasibility studies.¹⁸⁹ A literature review found that definitions of feasibility and pilot studies vary, but studies labelled 'feasibility' tend to use a flexible method compared with 'pilot' studies in practice. Arain *et al.*¹⁸⁸ suggest that feasibility studies are undertaken before a main study to 'estimate important parameters' for the design of a main study, such as the SD of the outcome measure for sample size calculation, characteristics and feasibility of the outcome measure, people's readiness to be recruited and randomised, number of eligible participants, adherence and follow-up rates. Feasibility studies should 'not evaluate the outcome of interest' but instead be powered to estimate parameters such as recruitment or dropout rates. Feasibility or external pilot studies assess one or more of the following:^{186,189}

1. the feasibility of key processes, such as eligibility criteria, and their ascertainment, randomisation procedures and their acceptability, retention and refusal rates, failure/success rates, adherence, appropriateness of the primary outcome measure or the acceptability of questionnaires
2. potential time and resource problems, such as administrative issues, staff training, the willingness and capacity of involved clinicians or centres, process times, for example for postage, preparing equipment, dealing with contingencies such as material breakdown, clinician absence
3. potential human and data management problems, including space for personnel and data collection forms, data entry and basic properties of the data such as missingness or variability
4. acceptability and safety of the intervention, dose, response, estimated treatment effect and estimated variance of the treatment effect for sample size calculation
5. the integrity of the study protocol.

We used a pragmatic approach to trial design with a specific emphasis on processes, to ensure external or ecological validity.^{190,191} The intervention was conducted in a routine GP setting (general practice or patients' homes), using little or no participant selection beyond being on a CHD register in the practice and the clinical indication of chest pain (exertional non-exertional) and depression, and specifically not excluding comorbidities that were common in general practice, such as diabetes, and may attenuate the treatment effect. This approach maximised real-world applicability of the findings, by allowing a direct translation of the outcomes to routine settings while also explaining processes occurring during the UPBEAT-UK intervention. The UPBEAT-UK intervention was manualised to allow fidelity evaluation, but was delivered with some degree of flexibility, for example with respect to session timing, to reflect real-world

practice and the interests of our two nurses [one (Mark Haddad) is a community psychiatric nurse who has worked clinically as a community psychiatric nurse in a local south London practice for 20 years and the other nurse (EB) is a registered general nurse and has a background as a respiratory nurse in a London teaching hospital with subsequent training as a chartered practitioner health psychologist and who currently works mainly as a nurse researcher]. Although our pragmatic trial design focused on effectiveness in the 'real world', a more explanatory RCT may have resulted in a clearer idea about what the active ingredients and causal processes may have been. However, it has been argued that pragmatism and understanding mechanisms should not be viewed as mutually exclusive¹⁹⁰ and our UPBEAT-UK findings should be able to answer both pragmatic and explanatory questions to some degree. The UPBEAT-UK pilot RCT was a pragmatic trial with explicit attention to processes, with several advantages and some disadvantages. We tested the intervention in everyday GP settings and one of the trial nurses (EB) chose to make home visits to build a better picture of the patient's environment.

One disadvantage and potential barrier to change we encountered was that the GPs and PNs in the south London practices proved sometimes to be harder to engage or contact than had been expected, and this had not been discussed in advance or built in to the study. For example, one of our GPs decided not to prescribe an antidepressant despite advice that this may be beneficial from one of the trial nurses after supervision with an academic GP (AT) and two psychiatrists (AM and PW).

Our pilot study was not designed to detect any improvement over and beyond TAU for depressive symptoms and well-being, as we were not testing treatment effect and were focused on testing feasibility and acceptability. Our patients in the pilot study prioritised managing pain, lack of exercise and sleep problems. Strategies for pain relief seem to have resulted in a reduction of reported chest pain although this would need to be tested in a definitive trial.

Minimisation of selection and allocation bias was addressed by random allocation by the independent King's Clinical Trials Unit. Randomisation appeared to achieve equal balancing of individual variables between groups. We reduced bias by collecting the baseline data before allocation. We addressed bias in the intervention by ensuring fidelity to the UPBEAT-UK pilot RCT manual was monitored to ensure that comparability of the intervention by our two nurses who jointly received weekly peer/group supervision (by AT, AM and PW). We minimised any bias in the follow-up data by ensuring that all participating patients were followed up and included in the analysis using an intention-to-treat approach to reduce the impact of selective attrition. We minimised bias in outcome data collection by the use of standardised objective assessments, rater training and supervision, and self-rating scales where possible and by using research assistants blind to treatment allocation.

A limitation common in similar trials was that blinding was achieved at only some levels: ideally the research participant, the care provider, the assessor and the statistician should all be blind. Although blinding participants and care providers prevents performance bias, that is, the preferential receipt of additional treatment in one group, it was not possible to achieve, as is so often the case.¹⁹² Blinding research assistants ensures independent judgement about outcome¹⁹³ but is difficult in practice, for example because participants disclose their allocation. We blinded our research assistants and asked them to record which group they thought participants were in and to notify us of any unblinding, which did happen on occasion. Our statistician became unblinded early on when the number of participants in the intervention group was mentioned in discussion – we had different numbers in each group (40 and 41) so it became obvious which group was which.

Although these methodological considerations are less relevant for the interpretation of a pilot study, such as UPBEAT-UK, non-blinded GPs and PNs, may cause post-randomisation confounding and biased outcomes through differential intensification of routine care in a definitive trial.¹⁹² Differential intensification may have occurred when participants in the experimental treatment were sensitised to certain issues and talked about them to their GP or nurse. Equally, GPs and nurses who knew about a person's assignment to the control condition and were convinced of the benefits of the experimental

treatment may have encouraged access to additional non-study care, leading to intensification of routine treatment in the control group and thus decreasing the effect size of the intervention. The choice of a control condition is important for the trial's internal validity, which can be threatened when the TAU group receives additional health-promoting behaviour, especially in trials of psychosocial interventions; although it is perfectly possible that the patients could have easily told their GPs or PNs if they saw them, there did not seem to be much interaction between them.¹⁹⁴ We used a TAU control and obtained printouts of GP consultations, referrals and treatment of both groups to assess what was received by the control group participants. As the UPBEAT-UK intervention was conducted independently of the usual GP practice staff, it is unlikely that there was any contamination. This would need careful consideration in any future definitive trial. TAU implies that anyone on GP CHD registers with chest pain and depression would routinely receive treatment, which may not be the case in reality. A more accurate term may have been 'usual care', which may or may not have happened. Comparing the UPBEAT-UK named nurse PC directly with existing general practice care for people on CHD registers with chest pain and depression may be problematic and may not even be possible if GP or nurse routine care involves individualised multiaspect multiprofessional case management for people with CHD and depression. It seems likely that we superimposed the experimental UPBEAT-UK treatment onto existing practice (whatever that is) to see if UPBEAT-UK nurse personalised case management has any potential added value that could be further tested in a definitive trial using a larger, more powered sample.

Recipients of UPBEAT-UK nurse PC would have received more attention (i.e. from the trial nurse) than the comparator group participants. They may have wanted to please their trial nurse after 6 months by inflating their self-rated improvement on the final outcome measure, which could be a possible limitation. Further non-specific factors may have been present, such as therapeutic alliance. We examined this by looking for any differences between our two nurses. A limitation of the study was that we did not record or rate consultations to assess alliance or attention. This makes it hard to assess the active ingredients.

Although our pilot was designed to assess feasibility and acceptability, rather than treatment effect on depression, a range of variables and events outside our PC may influence depressed mood. Confounding factors that have been empirically shown to impact on depression in people with CHD include medication changes, concurrent social problems and life events. Theoretically, these influences should be evenly distributed across randomised participants. However, their impact may still differ between groups depending on the chosen interventions and problems to be addressed. Hence, while it may be neither feasible nor necessary to control for all possible influences on depressed mood, a definitive trial might still aim to systematically assess the most prevalent influences on depressed mood. This would be a challenge, however, in a patient preference-led intervention such as UPBEAT-UK PC. Our GPs and nurses indicated that they knew that such problems abounded in their patients on CHD registers but were often at a loss to know what could be done about adverse social conditions.

All of these challenges will need to be addressed in a definitive RCT. Our pilot work does not address implementation issues involved in transferring the intervention to clinical practice. Use of a model such as May's Normalisation Process Theory¹⁹⁵ could be used to critically appraise the intervention. This would inform optimal implementation following demonstration of efficacy in a definitive RCT.

Work package 4

The aim of the cohort was to study the relationship over time between depression and symptoms of cardiac disease (chest pain) and outcomes (interventions, MI). We found the prevalence and incidence of depression to be lower than might be expected in such a cohort, but that of anxiety unexpectedly high. Nevertheless, the comorbidity of depression and anxiety in patients with CHD is worth taking into account, since patients suffering from conditions have a higher incidence of adverse outcomes and management strategies in these patients have so far failed to reduce this incidence.

It has long been noted that many patients referred for investigation of chest pain have concurrent anxiety and depression syndromes.¹⁹⁶ Chest pain is indeed a recognised symptom for the diagnosis of a panic attack.¹⁷³ Case-level anxiety or depression has been stated to be a contraindication to expensive cardiology investigation, as few are found to have coronary disease.¹⁷⁸ Most of the work on the association of chest pain with psychiatric disorders has been carried out in secondary care cardiology patients. To our knowledge there are few studies of the different types of chest pain experienced in people with known CHD in primary care. Our study population is different and there are no published studies on this topic in CHD register patients. In the UPBEAT-UK study, 44% of patients on GP CHD registers reported current chest pain. This was higher than previously reported.¹⁶² This is an important finding, although it could reflect a selection bias in the opt-in recruitment process. Two-thirds of the reported pain was exertional, suggesting cardiac origin, and exertional pain was a strong predictor of MI and death. These patients with continuing exertional pain are under primary care follow-up, but not all were referred to secondary care. There is potentially a case to be made for more emphasis on referral to secondary care, with patients continuing to report exertional chest pain during their primary care follow-up appointments.

Our study of associations at baseline shows that both exertional and non-exertional chest pain were associated with psychosocial factors such as depression and anxiety. Causality between chest pain and psychosocial factors cannot be determined during cross-sectional analysis. However, the great strength of this cohort data set is that it is longitudinal and multiwave. This allows us to be clearer about the direction of the association, and to see whether risk factors are equally powerful if they are distal (baseline) or proximal (last measured data point). To our knowledge, there is no previous study in which the Rose questionnaire has been used serially every 6 months for 3 years.

There is a different risk factor profile for those with exertional pain over this time, compared with the smaller proportion of people with non-exertional pain. For the former, baseline depression, anxiety and impaired quality of life play a part, with anxiety as the more dominant risk factor as it persists even after using multivariate models, which include quality of life. For non-exertional pain, the profile of females with asthma and shorter time on the register at baseline is the one more strongly associated.

Although anxiety may seem understandable in patients with CHD and chest pain, our study suggests that this may be a malign additional symptom that needs to be considered in addition to depression. Therefore, GPs and PNs monitoring these patients should be aware of the role of anxiety in addition to chest pain in predicting continuing suffering and decreased quality of life.

Limitations of the cohort methodology include the self-selection of the general practices participating and the selection by response rate of 27%. We cannot gauge the bias resulting from the response rate, as we were not allowed access to data on any patients who refused to participate. The patients were interviewed every 6 months, reporting on how they were currently as well as over the previous 6 months, introducing a possible recall bias. The 6-month intervals could be underestimating the number of experiences of anxiety and depression, as patients could have a brief episode of either condition, which we would not have detected by this method. The physical health information of these patients has come from patient recall, use of the Rose angina questionnaire and GP records. Each of these could inaccurately represent the health status of the patient. We did not have the resources to have a physical examination of each patient, hence the need to rely on these proxies.

The role and utility of general practitioner coronary heart disease registers for research

This was the first complex programme of research on patients registered on GP CHD registers. We have been unable to find comparable data from other studies, as most previous research has been conducted in secondary care settings. The advantage of using GP CHD registers is that patients are readily accessible through their GP practices, which maintain these registers, and this has been a key benefit to research from the advent of the QOF. This made it much simpler for us to recruit patients with CHD in a primary care setting. However, we tested the accuracy of the CHD registers with our cardiologist team members, an exercise which had not been done before, and we can report for the first time that the accuracy of CHD registers was approximately 85%. The registered population, we have discovered, contains a heterogeneous group in terms of the degree of CHD and cardiac intervention they have received, and recency or history of onset. Registers could also be used to select specific groups of patients (e.g. MI). This makes them a unique and epidemiologically enriched population to study the effect of any factors of cardiac outcome. Our sample was older, contained more males, had high levels of comorbidity (e.g. 25% diabetic), and multiple social problems and was less likely to be from black and minority ethnic communities. The sample, therefore, reflects a typical general practice population and thus differs from previous research in this area.

The disadvantage of using GP CHD registers for epidemiological research, however, is that the members are survivors. Consequently, there is a survivor cohort bias. The fact that our sample was 27% of the potential CHD register population was not because of the CHD registers but because of the required opt-in procedure. Unfortunately, we are unable to examine this bias because we cannot access information about or interview the patients who chose not to opt in to the research. This is a common problem in primary care research. It is possible that those patients who did opt in to UPBEAT-UK were more symptomatic in terms of chest pain and anxiety, and perhaps patients who did not opt in may have been more depressed than those who did opt in. If those who did opt in were less depressed, it is possible they felt that the trial was less relevant to them. This is cross-sectional so we cannot infer causality, but further modelling could help elucidate the complex inter-relationships and pathways between chest pain, anxiety and depression. Chest pain was found to reduce health-related quality of life, and further study is needed to fully understand the impact. It is noteworthy that our PC intervention was found to reduce the likelihood of reporting chest pain at both 6 and 12 months. Further research would require sophisticated modelling techniques that model hypothesised causal relationships.

The relative importance of anxiety and depression in this patient group

When we originally applied for funding there was a lot of interest in depression and CHD. While we found that there was a modestly high prevalence of depression, the high incidence rate and episodic nature was more noteworthy. Surprisingly, we did not find from our data any evidence that depression is a strong predictor of adverse cardiac outcome. This is not consonant with previous research from secondary care. This may reflect the characteristics and possible selection bias in our sample. On the other hand, the high prevalence rates for anxiety in our sample were unexpected. It is possible that more anxious people want to be recruited into such trials. Anxiety rates stayed high throughout the 36 months. Baseline anxiety disorder was a stronger predictor of adverse cardiac outcome and cardiac death than baseline depression. This finding needs further assessment and it is potentially very important for further research to examine the possible links between anxiety and cardiac pathology, as much previous research has focused on mechanisms linking depression and cardiac disease. These findings also have implications for clinical practice and raise questions about the need for anxiety being given equal emphasis with depression in terms of case finding. Our cohort data set could be used to develop a valid anxiety scale for use by practitioners to follow up people with anxiety and CHD.

In our pilot RCT, patients were helped by the nurses to prioritise perceived problems relating to their CHD and depression: one of the top five problems prioritised by the patients was anxiety (another of the top five problems was insomnia, which may have been anxiety related) and we also found some evidence of anxiety as a mediator for depression improvement. In a future trial, more active treatment, such as a more formal type of CBT or problem-solving treatment for anxiety and depression, should be tested, particularly when associated with chest pain.

The programme as a whole and how the findings from each of the work packages informed each other

This programme has been successful because of a multidisciplinary team with research and clinical backgrounds working together for over 6 years, combining qualitative and quantitative approaches in an active dialogue with regular meetings.

Some common features emerged from the varied approaches: the importance of social problems, chest pain as an unpleasant symptom with adverse effects, and depression and anxiety. While professionals often see the last two as independent conditions to pick out and treat, depression and anxiety are often not seen as such by patients. For patients, these conditions are merged with their physical ill health and social difficulties and they want an integrated approach to treatment. This inevitably locates their treatment best in primary care. We postulate that the method in our pilot RCT addresses the need for such an integrative approach. Motivation for patients is important, and the high patient adherence to our PC demonstrates the need for continuity of care from a case manager. Feedback from our trial participants showed how much continuity was appreciated. A combination of goal attainment and a focus on symptom resolution for chest pain, anxiety and depression seems important.

We were unable to employ PNs on the pilot RCT as originally intended because many of them informed us that they had no spare capacity, as well as considering themselves not to have the sufficient mental health or behavioural health training for such an intervention. It became apparent that a new intervention would need new integrated systems of care involving the whole practice team rather than depending entirely on one group of professionals or one treatment approach. Our nurses often found it difficult to contact members of the practice team and regular meetings with practice staff would have improved communication. PNs have a long tradition of case management for patients on registers (e.g. asthma, diabetes) and many would need enhanced training in behavioural management and psychosocial care.

There is current national interest in enhancing the role of IAPT to provide integrated care for patients with long-term conditions and 13 national pathfinder pilots are under way, one of which is in the area of CHD. Much of this role is likely to fall to PWP, who are often graduate psychologists with very little, if any, clinical training in relation to physical health problems (long-term conditions). PWPs, although well trained in providing low-intensity treatments and guided self-help approaches for anxiety and depression, would need much additional training and supervision in CHD prevention and management.

Our findings showed that overall costs were higher for those participants who were depressed at baseline, by approximately £5000 (i.e. almost double the cost of non-depressed participants). Differences between the two groups were significant across some services and non-significant across others, but the data highlight that people with depressive symptoms can use health services at a high rate and there are subsequent societal costs associated with this.

Conclusions

Nearly half of all patients on GP CHD registers were found to have current chest pain, and this was strongly associated with concurrent social problems. Patients who reported chest pain at the outset of the study were more likely to have further chest pain over the following 3 years and to have more adverse cardiac outcomes such as needing stent insertion, bypass graft surgery, having a MI or dying of a cardiac cause. While depression was common, episodic and associated with increased costs, anxiety disorder was more common and found to be a stronger predictor of worse cardiac outcome and mortality than depression.

Recommendations for further research

We propose several avenues for further research to build on our findings.

1. There is a pressing need to better understand the links. More sophisticated models linking the patterns of depression, anxiety and chest pain are needed to understand the associations between anxiety, chest pain and adverse cardiac outcome. We have a unique cohort data set to allow us to achieve this.
2. GPs and nurses seem currently uncertain how best to manage patients' symptoms in the context of the many psychosocial problems in their CHD patients. PC promoting self-management proved to be acceptable and feasible, improved patient self-efficacy, reduced chest pain and was associated with fewer overall costs than usual care (e.g. fewer A&E attendances). PC combining case management and self-management with an extra emphasis on anxiety needs to be further piloted and definitively tested with PN, working closely with colleagues in practices. Many nurses told us they had little extra current capacity so this would need to be built into practice plans.
3. PC combining self-management with an extra emphasis on anxiety could also be piloted and definitively tested with PWPs in IAPT although they would need training and supervision in long-term conditions and behavioural change techniques.
4. Further research should identify the training needs of staff to support the roll-out and deliverability of the intervention.
5. The cohort data set is available for further analyses for researchers both in and out of King's College London. Already we are collaborating with the Department of Psychological Medicine at King's College London (Professor M Hotopf) and with the Department of General Practice at the University of Amsterdam (Professor H van Marwyck). The longitudinal nature of the data makes them a rare and valuable resource for hypothesis testing. The analyses for this report, reflecting our funded aims, concerned anxiety and depression, and their relationship to cardiovascular outcomes. Other variables (e.g. physical comorbidity, social stresses and risk behaviours such as smoking and alcohol) were included as covariables in that relationship but not studied over time in their own right. To emphasise, CHD register patients are insufficiently studied, given the frequency of reported chest pain.
6. Self-reporting through the installation of an application on a mobile phone or tablet could allow patients to record each incident of chest pain with concurrent mood and social circumstances. This information would certainly inform GP management better than patient recall every few months and could lead to a patient's greater self-efficacy.
7. The result of the pilot RCT does not as yet justify a move to a larger trial but its acceptability and feasibility without additional cost suggest that these comorbid patients would appreciate this approach. We would propose, as the next step, another small feasibility study in which an IAPT worker was compared with a PN in the therapeutic role. An up-to-date metasynthesis should be carried out to inform this and the content of the intervention should be as effective for anxiety as for depression.

Implications for practice

The implications arising from these research results are for the primary care teams who follow up patients on the CHD register.

Chest pain in general and angina specifically remains a common experience in these patients despite the time that has elapsed since the event that placed them on the register. We have shown that chest pain produces high risk for another cardiac event. It is thus important that those reporting pain are not lost to follow-up in the practice.

Anxiety is more common than depression in these patients and, although usually comorbid with depression, is the more potent predictor of the two of subsequent cardiac events. Consideration could be given to the inclusion of the assessment of anxiety in these patients by the primary care team who could provide a strategy of management if necessary.

These older patients appreciated an approach to dealing with their low or anxious mood that focused on their own needs using psychological support. All the indications were that additional medication to that being taken for their physical conditions were unwanted.

The qualitative research suggested that a 'narrative of loss' underlay low mood in many patients. Their cardiovascular disease had led to loss of occupational role, social engagement or ability to be independent and in men loss of self-worth accompanying diminished sexual performance. This insight might enable a therapeutic point of contact to be established with some patients.

Acknowledgements

The coapplicants of the programme grant were: A Tylee, Department of Primary Care and Public Health Sciences, King's College London; M Ashworth, Department of Primary Care and Public Health Sciences, King's College London; J Chambers, Guys and St Thomas Foundation Trust, King's College London; M Leese, A Mann, P McCrone, J Murray, D Rose and P Walters, Health Service and Population Research Development, King's College London.

The wider UPBEAT-UK team members were: M Ashworth; J Brown, Institute of Psychiatry, Psychology and Neuroscience, King's College London; L Carvalho, University College London Research Department of Epidemiology; J Chambers; A Farmer, Institute of Psychiatry, Psychology and Neuroscience, King's College London; Z Fortune, Institute of Psychiatry, Psychology and Neuroscience, King's College London; M Haddad, City University London; S Hampshire, Institute of Psychiatry, Psychology and Neuroscience, King's College London; R Lawton, Institute of Psychiatry, Psychology and Neuroscience, King's College London; A Mehay, Prostate Cancer UK; J Mirza, Institute of Psychiatry, Psychology and Neuroscience, King's College London; N Nikkheslat, Institute of Psychiatry, Psychology and Neuroscience, King's College London; C Pariante, Institute of Psychiatry, Psychology and Neuroscience, King's College London; R Phillips, Singapore Clinical Research Institute; L Rolland, Institute of Psychiatry, Psychology and Neuroscience, King's College London; G Rowlands, Department of Primary Care and Public Health Sciences, King's College London; H Sims, Institute of Psychiatry, Psychology and Neuroscience, King's College London; and J Smith, Institute of Psychiatry, Psychology and Neuroscience, King's College London.

André Tylee was partly funded by the National Institute for Health Research Mental Health Biomedical Research Centre at the South London and Maudsley Foundation Mental Health Trust and the Institute of Psychiatry, Psychology and Neuroscience at King's College London.

We are grateful for the work of the UPBEAT-UK research assistant team: Aysha Begum, Sally Hampshire, Rebecca Lawton, Hannah Sims, Alison Smith, Joe Mirza, Zoe Fortune and Anita Mehay for collecting data from both patients and practices.

We would like to thank Professors Andrew Steptoe, Roger Jones, Peter Bower, Helen Lester and Christopher Dickens who provided independent Programme Steering Committee advice over the course of the programme.

The authors are grateful for the support and assistance of the PCRN-GL (Professors Gillian Rowlands and Brendan Delaney) and Dr Jo Burns in recruiting practices to the UPBEAT-UK study and to the 33 practices that kindly provided assistance with recruitment and ongoing support for the cohort and pilot RCT study. We would also like to thank the GPs and PNs from south London who agreed to be interviewed for the staff qualitative study and the 30 patients and their practices in south-east and south-west London for their help with the patient qualitative study. Above all, we would like to thank the 803 patients who agreed to be interviewed over 4 years, the 81 patients who took part in the pilot study and those who agreed to be interviewed for the qualitative studies.

We are particularly grateful to the UPBEAT-UK administrative staff: Julie Smith for overseeing the administration of UPBEAT-UK throughout the 6 years and Louise Rolland, who has joined in the last year and provided invaluable support for committees, oversight of financial statements and production of the final report.

Contributions of authors

André Tylee (Professor, academic general practice) was the chief investigator and was responsible for the design, conduct, supervision of entire programme team, interpretation of analysis and dissemination, drafting relevant chapters and co-ordination of the report including final draft after comments.

Elizabeth A Barley (Senior Lecturer, nursing) was responsible for the design, conduct, analysis and dissemination of the metasynthesis and qualitative study with professionals. Design, conduct as nurse care manager, interpretation of analysis and dissemination of pilot RCT. She was the UPBEAT-UK programme co-ordinator (last 2 years), overall interpretation of analysis and dissemination, drafting relevant chapters and commenting on full drafts.

Paul Walters (Consultant Psychiatrist, epidemiology) was responsible for the design, conduct, supervision of research assistants and trial nurses, analysis of cohort study and overall interpretation of other analyses and dissemination, drafting relevant chapters and commenting on full drafts. He was the UPBEAT-UK programme co-ordinator (first 4 years).

Evanthia Achilla (Research Fellow, health economics) was responsible for the design, conduct, analysis dissemination and drafting of the cost-effectiveness analysis.

Rohan Borschmann (Research Fellow, clinical psychology) was responsible for the interpretation of analysis and dissemination, editing of the report and commenting on relevant chapters.

Morven Leese (Emeritus Reader, biostatistics) was responsible for the design, conduct of statistical analysis and dissemination of results, drafting relevant chapters and commenting on full drafts.

Paul McCrone (Professor, health economics) was responsible for the design, conduct, analysis, dissemination and drafting of the cost-effectiveness analysis. He also commented on full drafts.

Jorge Palacios (Clinical Research Fellow, epidemiology) was responsible for the design, conduct, interpretation of analysis and dissemination of results. He also drafted and commented on relevant chapters.

Alison Smith (Research Fellow, social science) was responsible for the conduct of interviews, data collection, dissemination and commenting on relevant chapters.

Rosemary Simmonds (Research Associate) was responsible for the design, conduct and analysis of the qualitative study with patients. She also commented on relevant chapters.

Diana Rose (Professor, user-led research) was responsible for the design, conduct, analysis and oversight of the qualitative study with patients. She also commented on relevant chapters.

Joanna Murray (Senior Lecturer, health services and population research) was responsible for the design, conduct, analysis and oversight of the qualitative study with professionals. She also commented on relevant chapters.

Harm van Marwijk (Associate Professor, academic general practice) was responsible for the interpretation of the analysis, dissemination and commenting on full drafts.

Paul Williams (Research Fellow, biostatistics) was responsible for the design, conduct of the statistical analysis and dissemination of results. He also drafted and commented on relevant chapters.

Anthony Mann (Professor, epidemiological psychiatry) was responsible for the design, conduct, supervision of research assistants and trial nurses, interpretation of the analysis and dissemination of results, drafting relevant chapters, commenting on full drafts and co-ordination of report revisions.

Appendix 2 Checklist devised to assess the quality of observational studies

(Answer items 1–5 'yes' or 'no'.)

Screening: was there a clear aim?

1. Was the selection of participants appropriate? (Consider source population, inclusion or exclusion criteria, methods of selection.)
2. Was the measurement of variables appropriate? (Consider validity and reliability of instruments/ measures used.)
3. Was there appropriate control of bias? (Consider sources of bias, were appropriate methods outlined to deal with any issues such as recall bias, interviewer bias, non-responders, note response rate.)
4. Was the use of statistics appropriate? (Consider primary outcome stated a priori, note sample size.)
5. Was the study free of conflict of interest? (Consider declarations of conflict of interest or identification of funding sources.)
6. List any other limitations of the study.

Appendix 3 Topic guide for general practitioners and practice nurses

Context

Can you tell me a little about the practice and the population you serve?

Probes: SES [socioeconomic status], ethnicity, challenges, special interests, additional services, special interest in mental health, practice population size.

Coronary heart disease

How much of a problem is CHD in this practice?

Probes: high-risk groups; age; ethnicity; gender.

How do you manage your CHD patients?

Probes: recording, role of other professionals, frequency of visits, are there particulate difficulties in managing these patients?

Coronary heart disease and depression

Defining depression in coronary heart disease

It appears from research that many people with CHD may also be depressed. What is your experience of this?

Probes: direction of causality; which factors are important: symptoms, family, SES, gender, exercise; factors specific to CHD compared with other illnesses; do you routinely consider depression in these patients? Is it a special problem?

What are your views on the inclusion in the Quality and Outcomes Framework (QOF) of depression screening in patients with CHD?

Probes: is it a good/bad idea, workable in practice/difficult to do, relevant/irrelevant.

How would you make a distinction between distress and depression in someone with CHD?

Probes: for instance, distress that is perhaps a normal reaction to an adverse life event, and depressive illness that may require management? Criteria used; causes; patient factors; severity; course; outcome.

Do the patients share your views?

Current management of depression in coronary heart disease

Are you currently treating any of your patients for CHD and depression?

Probes: severity of CHD; severity of depression; risk factors; did the patient seek help for their depression? What was it about this patient that made you decide to treat them?

How do you feel about treating patients with CHD and depression?

Probe: is it any different from managing depression in other patients?

How do you/would you manage depression in someone with CHD?

Probes: available resources – medication, talking therapy, IAPT, lifestyle changes, complementary therapies, voluntary agencies, cardiac rehabilitation services; role of other professionals; successes; barriers; are there any issues specific to people with CHD compared with other illnesses? Is CHD treatment or depression treatment altered by comorbidity?

What would you hope to happen as a result of treating someone with CHD for depression?

Probes: improvement in mood; improvement in physical health; adherence to treatment; priorities.

What about discussing depression and treatment for depression with your CHD patients? Are there particular issues?

Probes: barriers; patient concerns; patient factors – ethnicity, gender, SES, age.

Future treatment of depression in coronary heart disease

We are aiming to design a programme of care for people with both CHD and depression. What options would you like to see included?

Probes: which would be most important? Who would deliver; role of other professionals/agencies; who would you refer; are any of these options especially suited to particular groups of patients? CHD specific versus generic.

Can you foresee any difficulties with any of the potential options?

How many of your current patients would benefit?

How do you think your CHD patients would feel about these options?

Any other issues

Finally, are there any other issues that we haven't addressed and that you would like to mention?

Appendix 4 Instruments used in the UPBEAT-UK programme

Two measures were included at the behest of local GPs as part of an agreement for co-operation. They (Psychological Outcome Profiles Questionnaire and Rapid Estimate of Adult Literacy in Medicine) were analysed separately and led to publications, which are listed in the acknowledgments.^{197,198} The third (Guy's Hospital Questionnaire) was suggested by the cardiologist on the team but was abandoned because it was too difficult to administer over the telephone.

Instrument	Author(s)	Description of instrument	Section of UPBEAT-UK used
BIPQ	Broadbent <i>et al.</i> , 2006 ¹²³	9-item scale designed to rapidly assess the cognitive and emotional representations of illness	Cohort study, RCT
Modified Rose angina questionnaire	Rose, 1962 ¹¹³	Questionnaire investigating on chest pain, which is widely used to determine the presence of angina in clinical populations	Cohort study, RCT
REALM	Davis <i>et al.</i> , 1993 ¹⁵⁶	A screening instrument designed to be used in public health and primary care settings to identify patients with low reading levels. It provides reading grade estimates for patients who read below a ninth grade level. The REALM can be administered in 1–2 minutes by personnel with minimal training	Cohort study
PSYCHLOPS	Ashworth <i>et al.</i> , 2004 ¹²²	PSYCHLOPS is a brief one-page mental health outcome measure and can be used during the course of any psychotherapeutic intervention. It is patient generated and can be self-completed. It has questions on problems, function and well-being	Cohort study
CSRI forms 1 and 2	Beecham and Knapp, 2001 ¹²⁷	The CSRI is a questionnaire for collecting retrospective information about study participants' use of health and social care services, accommodation and living situation, income, employment and benefits. The service receipt section is the largest part of the questionnaire. The data collected through the CSRI can be used to calculate service costs and total costs of care	RCT
SPQ	Corney and Clare, 1985 ¹²⁰	A brief self-report questionnaire identifying social problems, difficulties and dissatisfactions. The SPQ covers housing, occupation, finance, social and leisure activities, child/parent and marital relationships, relationships with relatives, friends, neighbours and workmates, and legal problems	Cohort study, RCT
Life events questionnaire	Brugha and Cragg, 1990 ¹⁵⁴		Cohort study
Short Form Questionnaire-36 items	McHorney <i>et al.</i> , 1993 ¹⁹⁹	The SF-36 is a multipurpose, short-form health survey with only 36 questions. It yields an 8-point scale profile of functional health and well-being scores as well as psychometrically based physical and mental health summary measures and a preference-based health utility index	Cohort study
SF-12	Ware <i>et al.</i> , 1996 ¹¹⁸	Abbreviated version of the SF-36 comprising only 12 items	RCT

Instrument	Author(s)	Description of instrument	Section of UPBEAT-UK used
EQ-5D	Hurst <i>et al.</i> , 1997 ¹²⁵	The EQ-5D assesses respondents' subjective quality of life – in reference to the assessment date only – across five life domains: mobility, self-care, usual activities, pain/discomfort and anxiety/depression. Overall health state is measured by a sixth item, which asks respondents to indicate their own health state on a scale from 0–100 (where 0 = 'the worst imaginable health state' and 100 = 'the best imaginable health state'). Respondents are asked to take into account both their physical health and mental health when indicating the overall health state	Cohort study, RCT
PHQ-9	Kroenke <i>et al.</i> , 2001 ¹¹⁶	Brief self-administered diagnostic instrument to detect depression	Cohort study, RCT
PHQ-2	Kroenke <i>et al.</i> , 2003 ⁸⁰	The PHQ-2 is a shorter version of the PHQ-9 with two screening questions to assess the presence of a depressed mood and a loss of interest or pleasure in routine activities; a positive response to either question indicates further testing is required	RCT
HADS	Zigmond and Snaith, 1983 ¹¹⁴	The HADS is a 14-item self-report scale for detecting states of depression and anxiety in outpatients. Respondents receive separate scores for depression and anxiety by summing scores from the appropriate items, with higher scores indicating higher levels of depression/anxiety. The HADS is useful for detecting change in a respondent's emotional state, as well as for assessing presence or absence of clinically significant degrees of anxiety and depression	Cohort study, RCT
General Health Questionnaire-12 item	Goldberg and Williams, 1988 ¹⁵¹	A self-administered screening questionnaire designed to detect those with a diagnosable psychiatric disorder	Cohort study
Specific Activity Scale	Goldman <i>et al.</i> , 1981 ¹¹⁹		Cohort study, RCT
Morisky Adherence Questionnaire – adapted version	Morisky <i>et al.</i> , 1986 ¹²¹	A structured four-item self-report adherence measure addressing the barriers to medication taking	RCT
List of Threatening Experiences Questionnaire	Brugha and Cragg, 1990 ¹⁵⁴	Brief questionnaire investigating the presence and impact of a range of common stressful life events on respondents	RCT
CIS-R	Lewis, 1994 ¹⁵²	Interviewer completed psychiatric assessment	Cohort baseline
Warwick–Edinburgh Mental Well-being Scale	Tenant <i>et al.</i> , 2007 ¹¹⁷	Self-report well-being scale	RCT
CSRI, Client Service Receipt Inventory; PSYCHLOPS, Psychological Outcome Profiles Questionnaire; REALM, Rapid Estimate of Adult Literacy in Medicine; SF-36, Short Form Questionnaire-36 items.			

Appendix 5 The UPBEAT-UK study cohort audit trail

18 July 2013

Summary:	Contains every action undertaken on the UPBEAT COHORT data set since receiving the data set
Original data sets:	J:\Programme Grant\Rachel\UPBEAT cohort\Data
Final data sets:	J:\Programme Grant\Rachel\UPBEAT cohort\Data\Final data sets
Syntax:	J:\Programme Grant\Rachel\UPBEAT cohort\Data\Syntax
Other information:	J:\Programme Grant

Data version	Action	Syntax file
--------------	--------	-------------

1 Data set set up (separately for each time point)

Original data sets downloaded from MACRO by the Data Manager (Christopher Rowson) and emailed as a .csv file
 Rachel Phillips was responsible for receiving all extractions up to and including the 24-month data
 RP also wrote the instructions for cleaning the data sets and data checking processes
 Paul Williams took over for the 30-month until 48-month (final) data sets, using these instructions
 Original data sets as .csv files can all be found in the 'Data' folder under the relevant subfolders
 Paul Williams was also responsible for collating the data sets and merging in any additional data

1.1 Data cleaning and scale scoring

The same operations were undertaken for each data extraction (each time point)
 All data cleaning were carried out in STATA version 11.2

The instruction document (**Document to outline the ordering of do files for UPBEAT data.doc**) describes the cleaning process that transforms the .csv file into a cleaned STATA data set. e.g. for 30 month:

30month_UPBEAT_Live20120821.csv	Extraction to STATA format	0_insheets_30months.do
thirty_month.dta	Full cleaning process (including the start of data cleaning)	1_30month.do

Data version	Action	Syntax file
1.2	Data checking	

The instruction document (**Document to outline the ordering of do files for UPBEAT data.doc**) also describes the data checking process that checks for: data entry errors, correct number of participants, correct dates for the time between baseline and time point)

Any data errors that were flagged when conditions were not met were noted in the document (**upbeat data discrepancies v2.2.xlsx**) and amendments were written into the cleaning.do file)

e.g. for 30 months:

30month.dta	Data errors flagged, recorded and amendments made to.do file	1_30month.do
-------------	--	--------------

A list of ID numbers was then obtained and this was checked by the researchers to see whether or not this list matches the list of participants recorded on the ACCESS database

Any mis-matches flagged were recorded in the document (**Access and Macro Follow ups at 30months FIXED.docx**) and also (**Date discrepancies CORRECTIONS.doc**)

Any resulting amendments were translated into STATA code and the STATA data set was changed accordingly

30month.dta	Changes to be made to the participants in the data set of the time point	30m_amendments.do
-------------	--	-------------------

If in the case the interview had been stored in the incorrect time point, the same.do file (30m_ammendments.do) extracts the data set, places it in the correct folder, and merges the record into the correct time point. In which case, the record would be stored as a separate data set in that folder, e.g.:

30month_P14007.dta

Correct dates of the interviews were checked by calculating differences between their interview date and the interview date of their baseline visit. Any participants with substantial differences (> 1 month early, > 4 months late) were investigated

All reporting of date errors was recorded in the document (**Date discrepancies CORRECTIONS.doc**)

30month.dta	Merge 30 month and baseline time point variables and create merged data set called base_30month.dta	Merging 30 months.do
base_30month.dta	Check time difference between time points, check outliers with researchers	initial_30months.do
30month.dta	Make amendments to data set, resulting in a cleaned final data set with the same name	30month_correctdates.do

A data cleaning checklist was compiled to keep track of progress for weekly meetings (**Data cleaning check.xlsx**)

2 **data set set up (complete cohort data set)**

The process for combining the data sets was as follows: (1) make all the data sets (of each time point) compatible; (2) create a variable to distinguish the data sets; then (3) append these data sets

By appending data sets of the same observations, and mostly the same variables but different time points, we essentially create a data set in long format with many rows per participant. Matching occurs on the variables, not the unique identifiers as is normally done with merging. Appending has the advantage in this instance of creating a data set with fewer variables than what would have been produced in the wide format

1. Making the data sets compatible

Data version	Action	Syntax file
For each data set, variable names were shorted to remove the suffix containing the time point information		
Any variable names that were not the same in all the time points were renamed accordingly for synchronisation		
PYSCHLOPS variables that contained information about previous time points were dropped		
Data sets used were from the folder: (J:\Programme Grant\Rachel\UPBEAT cohort\Data\Final data sets)		
base_medic_complete.dta		
6month.dta		
12month1.dta		
18month.dta		
24month.dta		
30month.dta		
36month.dta		
42month.dta		
48month.dta		
2. Create a variable to distinguish time points		
The variable <time point> was created, containing sequential values per data set (per time point)		
data sets were saved locally		
base.dta

30.dta		
36.dta		
42.dta		
48.dta		
3. Append these data sets		
All data sets were appended to the master data set (baseline) simultaneously.		
base	append all other time points into this data set, and save as upbeat_cohort.dta	upbeat_cohort_merge.do

Data version	Action	Syntax file
2.1	<i>Data cleaning and scale scoring</i>	

The process of data cleaning on the cohort data set involved (1) dropping all empty fields, (2) renaming and ordering variables appropriately, (3) ordering the data by patid and time point, and (4) inserting information into missing fields (e.g. gender was only recorded at baseline and so this information was carried across to other time points)

upbeat_cohort.dta	Data cleaning (1–4)	upbeat_cohort_clean.do
	HADS anxiety missing values (> 55) to be classed as missing on variables (hads_anx anx_cat anx)	upbeat_cohort_clean.do
	Create ROSE classifications variable (called rose_short)	upbeat_cohort_clean.do
	Labels for GP practices	upbeat_cohort_clean.do
	Relabeling age variables to make explicit these were age at baseline (demographics questions collected only at baseline). The creation of a new age variable to record participant age throughout the data collection	upbeat_cohort_clean.do
	Relabeling comorbidity variables to make explicit these were age at baseline (demographics questions collected only at baseline)	upbeat_cohort_clean.do
upbeat_cohort.dta	Check to see whether or not the all dates and time point make sense	upbeat_cohort_inspec.do

2.2 ***Merging additional data: (1) loss information (2) cardiac investigations information (3) depression pattern information***

Data from sources other than MACRO were entered into the cohort data set as follows

2.2.1 ***(1) Loss information***

Information regarding [(1) deaths, (2) withdrawals, and (3) loss to follow ups] on the whole sample was collected by Alison Smith and Rebecca Lawson

Specific categories were decided upon during weekly UPBEAT meetings with the whole team

Data was entered onto an excel spreadsheet (**Cohort Main Spreadsheet – Deaths,LTFU,Withdrawal.xlsx**)

The codebook for reasons of drop out is reported in the document (**CODES FOR COHORT.doc**)

Data was imported into the upbeat cohort, with the following specification:

1. The addition of variables describing reasons for drop out. Deaths are coded in a separate variable to loss to follow up and withdrawal. Also note that this has been split further into variables to use for a 36-month analysis and for a 48-month analysis. This is because if someone died at 42 months, they would be included as alive in the 36-month analysis but not at the 48-month analysis
2. The variable <loss_event> classifies records into whether or not an event has been recorded that has resulted in their permanent removal from the study (i.e. does not participate at a later date)

Data version	Action	Syntax file
<p>3. Due to the coding of these events to replicate the sampling design (i.e. every 6 months), deaths were recorded at the time point at the end of the 6-month 'waiting' window. I.e. if Person A was measured in July (baseline), January (6 months) then died in March; this would be coded into the July time point. This is needed for the longitudinal analyses. For the survival analyses, specific dates are given for each event</p> <p>4. As a result of point 3 above, additional records have been created to contain these events. Using the same example as above, Person A would have records for baseline, 6 months and 12 months. If Person A died the following year he would have records for baseline, 6 months and 24 months</p> <p>5. The variable used to define the individual sampling windows was <visit_date_hyp> (hypothetical visit date). This is essentially the corrected visit date <visit_date_c> i.e. date of interview, with 6-month additions (from baseline visit date) for each time point that was missing</p> <p>6. Withdrawals were coded into the nearest time point that satisfied the criteria 2 months<withdrawal or LTF< 4 months. This was because by the nature of this sort of event, it must have only occurred for the time period for which contact was attempted to be made. The reason for the skewed window was to allow up to 4 months of recon acting. Dates are attached to each event so as to allow the most accurate time data for survival type analyses</p> <p>7. There is no '56 month' time point as only 4 deaths and would have populated this time point, and the dates of these events were relatively close to the 'hypothetical visit date' (within a few months) and considering there was a window of 1 month before to 4 months after for a participant to be contacted, I do not think this misrepresents the data. Creating a new time point may be misleading</p>		
upbeat_cohort.dta	Merge in the Loss data from (Cohort Main Spreadsheet – Deaths,LTFU,Withdrawal.xlsx)	upbeat_cohort_loss.do
	Fill in demographic data into these new records	upbeat_cohort_loss.do
	Save data set as upbeat_cohort_v2.dta	upbeat_cohort_loss.do

2.2.2

(2) Cardiac investigation information

Information regarding cardiac investigations were collected from the GP notes for every participant in the cohort study and were inputted into an encrypted Microsoft Access database by Dr Jorge Palacios (**Upbeat_Cohort_Med_Notes_2.mdb**)

The specific data to be inputted and the specific definitions of cardiac investigations were decided before the hard copies were examined, with exception to the 'Rapid Access Clinic' category*. It was decided that data on rapid access would provide important information as to the severity of chest pain problems that a participant was experiencing (by the reasoning that if they used this service, then they must have experienced a level of severity higher than 'ROSE Exertional pain' but lower than the severity that required an intervention or even the severity defined by a cardiac event. This was decided upon by the UPBEAT team during weekly meetings. The GP notes were re-examined to gather this information and all data were inputted into the Access database before any analysis of cardiac investigation data occurred

* It was later suggested by the UPBEAT team that this 'Rapid Access' classification may not provide information regarding cardiac severity in the manner it was first thought to, and suggestions were made to remove it due to the following reasons: (1) it presented a very heterogeneous group of participants who had various reasons for accessing rapid access, of which the reasons were not recorded; (2) the results from the Rapid access service were not recorded so this could not be validated. Based on these two reasons, it cannot be used to determine with adequate accuracy the severity of heart problems as the other categories; and (3) participants access to the service was disparate among locations (as defined by GP practice) leading to potentially biased results dependent on where the participant lived

Access data was exported to a STATA data set file (**data_cardiac_investigations.dta**)

A codebook for the cardiac investigations was saved as a STATA data set file (**tbl_cardiac intervention type.dta**)

Data was imported into the upbeat cohort before any analysis, with the following specification:

1. Data were available for every cardiac investigation per participant from 2005 (earliest example) until the data the notes were collected. Participants could therefore have a large number of candidate records that could be fit into multiple time points
2. To simplify this information, it was decided by the team that the investigations should be recorded in two ways (1) the first cardiac investigation to occur within two time points would be recorded per person, and (2) the most severe cardiac investigation to occur within two time points would be recorded per person

Data version	Action	Syntax file
<p>3. For consistency with the coding of other event data (deaths), cardiac investigations were coded into time points in the same manner – recorded into the time point at the end of the 6-month ‘waiting’ window between interviews. I.e. if Person A was measured in July (baseline), accessed rapid access in August, had a MI in September, and then interviewed again in January (6 months): the coding under the ‘first’ definition would place the rapid access event into the January (6 month) time point. The coding under the ‘severe’ definition would place the MI event into the January (6 month) time point</p> <p>4. A difference between this data and the deaths data was that if a participant had a recorded cardiac investigation before baseline (exactly 6 months window leading up to baseline); this was allowed to be recorded in the baseline time point</p> <p>5. Ordinal variables were created to define severity of heart problems. This was defined a priori to any analysis*. The ordinal variable had the following construction:</p> <p>0 no chest pain 1 chest pain 2 exertional chest pain 3 rapid access 4 Bypass graft or angioplasty 5 MI 6 Cardiovascular death</p> <p>The classification of a participant within a time point depended on their most severe data for that time point. Cardiovascular deaths (cardiac/stroke/vascular) were chosen over cardiac only deaths due to low numbers in order to increase statistical power. This ordinal variable was duplicated for the two definitions of cardiac investigation (1) first (2) severe. *After discussions regarding the appropriateness of the ‘rapid access’ classification, the two versions (first and severe) classifications were split further to include/exclude this rapid access</p>		
data_cardiac_investigations.dta	Clean data and save data set as cardiac_all_wide.dta	upbeat_cohort_cardiac outcomes
upbeat_cohort_v2.dta	Keep only variables: (id, time point and visit date). Reshape wide. Merge in the cardiac investigations data (cardiac_all_wide.dta)	upbeat_cohort_cardiac outcomes
	Visit dates for time points 0 (baseline) – 8 (48 months) were available in wide format. An additional variable was created to mark the date exactly 6 months prior to their baseline visit. All cardiac investigations were assigned to their appropriate time point based on the window (Tn-1 to Tn)	upbeat_cohort_cardiac outcomes
	These cardiac investigations were then used to create the appropriate variables (1) first investigation per person per time point was coded into a variable, and (2) the most severe investigation per person per time point was coded into another variable. Dates of such investigations were retained alongside each of these. All other information was dropped. This data set was saved as cardiac_long.dta	upbeat_cohort_cardiac outcomes
	Merge in the cardiac investigations data (cardiac_long.dta)	upbeat_cohort_cardiac outcomes
	Outcome variables created for the ordinal cardiac problems (from no chest pain – chest pain – cardiac investigations – cardiovascular death). The two versions utilise the two definitions of cardiac investigation (1) first in time point (2) most severe in time point	upbeat_cohort_cardiac outcomes
	Cleaning of variables as new records per person were added	upbeat_cohort_cardiac outcomes
	Save data set as upbeat_cohort_v3.dta	

Data version	Action	Syntax file
2.2.3	(3) Depression pattern information	

Depression episodes as defined by the HADS depression scale (cut off 8 or more = positive) were extracted from the upbeat cohort into an Excel spreadsheet for the purpose of descriptively reporting the patterns of depression throughout the cohort up to 36 months

It was decided by the team that the combination of different patterns (start, end, fluctuating) and missingness should be collapsed as succinctly as possible

These coding for this was performed in Microsoft Excel in the file (**depression table with analysis 2.0.xls**)

A version of this that contained only the information on patterns and missingness was saved as a comma delimited file to be imported into STATA (**dep_pat.csv**)

The 3 variables chosen to describe a participant's pattern of depression episodes were

1. Pattern: consisting of 6 different patterns, labelled in a way to describe depression at baseline, depression at 36 months (4 patterns) and 2 patterns describing fluctuating episodes
2. Missingness: marking whether or not there was any missing data during the 36 months and where the missing data occurred
3. Any depression: marking whether or not any episodes of depression were recorded

upbeat_cohort_v3.dta	Merge in the patterns data from (dep_pat.csv)	upbeat_cohort_dep_patterns
	Data cleaning	upbeat_cohort_dep_patterns
	Save data set as upbeat_cohort_v4.dta	upbeat_cohort_dep_patterns

3 **Creating a wide version of the data set**

To create a wide data set, first the long data set needed to be reduced as it contained 940 variables. A wide version of which would contain (8 × 940 variables) and it was decided appropriate to reduce this for simplicity

The method for creating a wide version of the data set consisted of (1) retaining only key variables, (2) add suffix ' _ ' to the end of variable names, and (3) reshape wide

A list of key variables of immediate interest was selected to be retained in the wide version of the data set (to save space). These variables along with others as requested were retained

upbeat_cohort_v4.dta	(1) retain only the key variables	upbeat_cohort_wide.do
	(2) add suffix ' _ ' to the end of variable names	upbeat_cohort_wide.do
	(3) reshape wide	upbeat_cohort_wide.do
	Save data set as upbeat_cohort_v4_wide.dta	upbeat_cohort_wide.do

A decorative graphic consisting of numerous thin, parallel green lines that curve from the left side of the page towards the right, creating a sense of movement and depth.
